ABSTRACT
Future X-ray observations of galaxy clusters by high spectral resolution missions will provide spatially resolved measurements of the energy and width for the brightest emission lines in the intracluster medium (ICM) spectrum. In this paper we discuss various ways of using these high-resolution data to constrain velocity power spectrum in galaxy clusters. We argue that variations of these quantities with the projected distance $R$ in cool core clusters contain important information on the velocity field length scales (i.e. the size of energy-containing eddies) in the ICM. The effective length $l_{\text{eff}}$ along the line of sight, which provides dominant contribution to the line flux, increases with $R$, allowing one to probe the amplitude of the velocity variations at different spatial scales. In particular, we show that the width of the line as a function of $R$ is closely linked to the structure function of the 3D velocity field. Yet another easily obtainable proxy of the velocity field length scales is the ratio of the amplitude of the projected velocity field (line energy) variations to the dispersion of the velocity along the line of sight (line width). Finally the projected velocity field can be easily converted into 3D velocity field, especially for clusters like Coma with an extended flat core in the surface brightness. Under assumption of a homogeneous isotropic Gaussian 3D velocity field we derived simple expressions relating the power spectrum of the 3D velocity field (or structure function) and the observables. We illustrate the sensitivity of these proxies to changes in the characteristics of the power spectrum for a simple isothermal $\beta$-model of a cluster. The uncertainties in the observables, caused by the stochastic nature of the velocity field, are estimated by making multiple realizations of the random Gaussian velocity field and evaluating the scatter in observables. If large-scale motions are present in the ICM these uncertainties may dominate the statistical errors of line width and shift measurements.

1 INTRODUCTION
Properties of gas motions in the hot intracluster medium (ICM) are still little known. It is believed that turbulent motions are driven when matter accretes on to the filaments or during shocks in the hot gas. Turbulence transfers kinetic energy injected on large scales $L \sim \text{Mpc}$ to small (unknown) dissipative scales $l$. These two scales are connected with a cascade of kinetic energy, which occurs over inertial range (Kolmogorov 1941; Landau & Lifshitz 1966).

*E-mail: izhur@mpa-garching.mpg.de

Knowing the properties of gas motions in clusters, we would be able to address a number of important question, e.g. what is the bias in the cluster mass measurements based on hydrostatic equilibrium and whether the bias is due to the motions alone or due to the clumping in gas density (see e.g. Rasia et al. 2006; Nagai, Vikhlinin & Kravtsov 2007; Jeltema et al. 2008; Lau, Kravtsov & Nagai 2009), what is the ICM turbulent heating rate in clusters (e.g. Churazov et al. 2008) and what is the role of gas motions in particle acceleration (see e.g. Brunetti 2006; Brunetti & Lazarian 2011).

Properties of turbulence in galaxy clusters were studied by means of numerical simulations (e.g. Norman & Bryan 1999; Cassano & Brunetti 2005; Dolag et al. 2005; Iapichino et al. 2011; Vazza et al. 2011). However despite the good ’global’ agreement between all
Current generation of X-ray observatories cannot provide robust direct measurements of turbulence in the ICM. Only reflecting grating spectrometer on the XMM-Newton satellite (XMM RGS) can provide weak upper limits on velocity amplitude in cool core clusters (Sanders, Fabian & Smith 2011). Indirect indications of the ICM turbulence come from measurements of the resonant scattering effect (e.g. Churazov et al. 2004; Werner et al. 2009), from measurements of pressure fluctuations (Schuecker et al. 2004) or from surface brightness fluctuations (Churazov et al. 2012).

Future X-ray observatories, such as Astro-H1 and ATHENA,2 with their high energy resolution will allow us to measure shifts and broadening of individual lines in spectra of galaxy clusters with high accuracy. Combination of direct measurements of velocity amplitudes with indirect measurements via resonant scattering will give us constraints on anisotropy of motions (Zhiravleva et al. 2011). X-ray polarimetric measurements can also provide information on gas motions perpendicular to the line of sight (Zhiravleva et al. 2010).

Here we discuss the possibility of getting information about the length scales of gas motions (e.g. the size of energy-containing eddies). We discuss various ways to constrain structure function (SF) and power spectrum of gas motions via measurement of the projected velocity (shift of the line centroid) and the velocity dispersion (broadening of the line) as a function of projected distance from the cluster centre. These ideas are illustrated with a very simple model of a galaxy cluster. An application of our methods to simulated galaxy clusters will be considered in future work.

A similar problem of obtaining the SF of turbulence from spectral observations has been addressed in the studies of Galactic interstellar medium. In particular, it was shown that the width of molecular spectral lines increases with the size of a cloud (see e.g. Myers et al. 1978; Heyer & Brunt 2004; Heyer et al. 2009). This correlation was interpreted in terms of turbulent velocity fluctuations with indirect measurements via resonant scattering will give us constraints on anisotropy of motions (Zhiravleva et al. 2011). X-ray polarimetric measurements can also provide information on gas motions perpendicular to the line of sight (Zhiravleva et al. 2010).

The ISM turbulence is often supersonic and compressible (e.g. Elmegreen & Scalo 2004). This leads to (i) large shifts in the energy centroid of the line compared to the thermal broadening and (ii) large amplitude of the gas density fluctuations. At the same time individual lines, which are used to study the ISM turbulence (e.g. 21 cm line of H I or CO lines), are often well separated from other emission lines. The regions under study often have very irregular structure on a variety of spatial scales. The analysis therefore is usually concentrated on separation of the velocity and density fluctuations in the observed data, while the thermal broadening can often be neglected.

In contrast, in galaxy clusters the gas motions are mostly subsonic. The detection of the gas motions is still possible, since we deal with the emission lines of ions of heavy elements like Fe, Ca or S. The atomic weights of these elements are large (e.g. for Fe it is 56) and this drives pure thermal broadening of lines down (see Fig. 1 and Section 7.2). The brightest lines in spectra of galaxy clusters are often very close to each other. For example, in the vicinity of the He-like iron line at 6.7 keV there are forbidden and intercombination lines and a number of satellite lines, energy separation between which is of the order of few tens of eV (Fig. 1). Density of clusters often has a regular radial structure with relatively small amplitude of stochastic density fluctuations. An analysis of X-ray surface brightness fluctuations in Coma cluster shows that density fluctuations are ~2–10 per cent (Churazov et al. 2012). Also hydrodynamical simulations of cluster formation predict very small clumping factors within r500 (see e.g. Mathiesen, Evrard & Mohr 1999; Nagai & Lau 2011). Therefore, to the first approximation, the contribution of density fluctuation in galaxy clusters can be neglected (see Section 7.4 for details), while global radial dependence has to be taken into account (Section 4). Another characteristic feature of X-ray observations is the importance of the Poisson noise, related to the counting statistics of X-ray photons. If one deals with

---

**Figure 1.** Simulated spectrum of the Perseus cluster core (central 130 kpc), calculated assuming different Mach numbers of the turbulence. At each point along the line of sight the locally emitted spectrum is calculated using Astrophysical Plasma Emission Code (APEC; Smith et al. 2001) model and using known radial density and temperature dependencies. The lines are then broadened by the thermal and turbulent motions using equation (24) (see Section 7.2) and the whole spectrum is projected along the line of sight. The case of pure thermal broadening of lines is shown in black. This plot shows that (i) turbulent broadening is important even for the modest level of turbulence and (ii) lines overlap with each other, especially if turbulent motions are present.
the clusters outskirts, then the high energy resolution spectra will be dominated by the Poisson noise even for large area future telescopes, like ATHENA.\footnote{http://sci.esa.int/ixo} Finally, one can mention that the effects of self-absorptions can potentially be important in clusters. Galaxy clusters are transparent in X-rays in continuum and in most of the lines. However, some strong lines can have an optical depth of \sim{} few units. Therefore if one measures the width of the optically thick line distortions due to resonant scattering effect should be taken into account (see e.g. Werner et al. 2009; Churazov et al. 2010; Zhuravleva et al. 2011; de Plaa et al. 2012).

The presence of several closely spaced emission lines, modest level of turbulence (i.e. modest ratio of the turbulent and thermal broadenings), the lack of very strong stochastic density fluctuations on top of a regular radial structure, and often a strong level of Poisson noise affect the choice of the simplest viable approach to relate future observables and most basic characteristics of the ICM gas velocity field.

The fact that lines in spectra of galaxy clusters are very close to each other (e.g. Fig. 1) and the line ratio is temperature dependent can be circumvented by estimating the mean shift and broadening with direct fitting of the projected spectra with the plasma emission model (possible multi-temperature model). While the small thermal broadening of lines from heavy elements helps to extend the applicability of VCA/VCS techniques into the subsonic regime (see Esquivel et al. 2003; Lazarian & Esquivel 2003; Chepurnov et al. 2010), limited spectral resolution of the next generation of X-ray bolometers [e.g. full width at half-maximum (FWHM) \sim{} 5 eV for Astro-H] reduces the measured inertial range in the velocity domain. Direct application of SCF and PCA methods to galaxy clusters can also be challenging, especially when the spectra are dominated by the Poisson noise. These problems should be alleviated with missions like ATHENA, having very large effective area and an energy resolution of \sim{} 2.5 eV.

Below we suggest to use the simplest ‘centroids and broadening’ approach as a first step in studying the ICM turbulence. This approach assumes that at any given position one fits the observed spectrum with a model of an optically thin plasma (including all emission lines) and determines the velocity centroid and the line broadening. This reduces the whole complexity of X-ray spectra down to two numbers – shift and broadening. A simple analysis of existing hydrodynamic simulations of galaxy clusters shows that this approximation does a good (although not perfect) job in describing the profiles of emission lines (see e.g. fig. 2 in Inogamov & Sunyaev 2003). At the same time this approach is the most effective in reducing the Poisson noise in the raw measured spectra. We show below that in spite of its simplicity this approach provided an easy way to characterize the most basic properties of the ICM velocity field.

Clearly, more sophisticated methods developed for the ISM turbulence (e.g. Lazarian 2009) will eventually be adopted to the specific characteristics of the ICM turbulence and X-ray spectra, potentially providing a more comprehensive description of the ICM turbulence, once the data of sufficient quality become available.

The structure of the paper is as follows. In Section 2 we describe and justify models and assumptions we use in our analysis. In Section 3 we specify observables which can be potentially measured and their relation to the 3D velocity power spectrum. Section 4 shows the relation between observed velocity dispersion and the SF of the velocity field. A way to constrain length scales (size of the energy-containing eddies) of motions using observed projected velocity is presented in Section 5. Method to recover 3D velocity power spectrum (PS) from 2D projected velocity field is discussed in Section 6. Discussion and conclusions are given in Sections 7 and 8, respectively.

## 2 BASIC ASSUMPTIONS AND MODELS

We consider a spherically symmetric galaxy cluster, which has a peaked X-ray emissivity profile. The electron number density is described by the \(\beta\)-model profile

\[
  n_e(r) = \frac{n_0}{\left[1 + \left(\frac{r}{r_c}\right)^2\frac{2\beta}{\gamma}\right]^{\frac{1}{2}\beta}},
\]

where \(n_0\) is the electron number density in the cluster centre (normalization) and \(r_c\) is the core radius. The \(\beta\)-model provides a reasonably good description of observed surface brightness (Cavaliere & Fusco-Femiano 1978) in the central regions of galaxy clusters. At large radii \(\beta\)-model is not a good description of surface brightness (see e.g. Vikhlinin et al. 2006). However, the simplicity of the model allows us to illustrate the method and make analytical calculations.

We have chosen \(\beta = 0.6\) and \(r_c = 10\) kpc for the demonstration of our analysis. Parameter \(\beta\) usually varies \(0.4 < \beta < 1\) for galaxy clusters (see e.g. Chen et al. 2007), herewith a large fraction of clusters have \(\beta \sim 0.6\). \(r_c\) can vary from a few kpc to a few hundreds kpc. In order to better illustrate the main idea of the method, we considered cool-core clusters with small core radius \(r_c\) (it is necessary to have a gradient of surface brightness down to the smallest possible projected distances; see Section 4 for details).

We describe the line-of-sight component of the 3D velocity field as a Gaussian isotropic and homogeneous random field. This allows us to gauge whether useful statistics could in principle be obtained. However, there is no guarantee that this assumption applies to the velocity field in real clusters. For example, Esquivel et al. (2007) using numerical simulations have shown that in the case of super-sonic turbulence in the ISM, the non-Gaussianity causes some of the statistical approaches (based on the assumption of Gaussianity) to fail. The same authors demonstrated that for the subsonic turbulence the Gaussianity assumption holds much better. This is encouraging since in clusters we expect mostly subsonic turbulence. Nevertheless, the methods discussed here require numerical testing using galaxy clusters from cosmological simulations. We defer these tests for future work.

PS of velocity field is described by a cored power-law model\footnote{Here and below we adopt the relation between a wavenumber \(k\) and a spatial scale \(x\) as \(k = 1/x\) (without a factor 2\(\pi\)).}

\[
  P_{\text{3D}}(k_x, k_y, k_z) = \frac{B}{\left(1 + \frac{x^2 k_m^2 + y^2 + z^2}{k_c^2}ight)^{a/2}},
\]

where \(k_m\) is a break wavenumber (in our simple model \(k_m\) characterizes the injection scale), \(a\) is a slope of the PS at \(k > k_m\) (inertial range) and \(B\) is the PS normalization, which is defined so that the characteristic amplitude \(A\) of velocity fluctuations at \(k = k_{\text{ref}}\) is fixed, i.e.

\[
  B = \frac{A^2}{4\pi k_{\text{ref}}^2 P_{\text{3D}}(k_{\text{ref}})}.
\]
The cored power-law model of the PS is a convenient description of the PS for analytical calculations and at the same time resembles widely used broken power-law model.

Now let us specify the choice of parameters $\alpha$ and $k_m$ in the model of the velocity PS. Cluster mergers, motions of galaxies and active galactic nuclei (AGN) feedback lead to turbulent motions with eddy sizes ranging from Mpc near the virial radius down to a few tens of kpc near the cluster core (see e.g. Sunyaev, Norman & Bryan 2003). For our analysis we vary injection scales from 20 kpc ($k_m = 0.05$ kpc$^{-1}$) to 2000 kpc ($k_m = 0.0005$ kpc$^{-1}$).

Parameter $\alpha$ – the slope of the PS – can be selected using standard arguments. If most of the kinetic energy is on large scales (injection scales), i.e. the characteristic velocity $V$ decreases with $k$ then the power spectrum $PS = V^2/k^\alpha \propto k^\alpha$ with $\alpha \leq -3$. At the same time the turnover time of large eddies should not be larger than the turnover time of small eddies, i.e. $t = l/V = 1/(kV)$ is a decreasing function of the wavenumber $k$. Therefore, $V \propto k^{\beta}$ with $\gamma \geq -1$ and PS $\propto V^2/k^\alpha \propto k^\alpha$ with $\alpha \geq -5$. So we expect the slope of the PS to be in the range $-5 \leq \alpha \leq -3$. We will use $\alpha = -11/3$ (slope of the Kolmogorov PS), $\alpha = -4$ and $\alpha = -4.5$.

3 OBSERVABLES AND 3D VELOCITY POWER SPECTRUM

Gas motions in relaxed galaxy clusters are predominantly subsonic, and to the first approximation the width and centroid shift of lines measured with X-ray observatories contain most essential information on the ICM velocity field (see e.g. Inogamov & Sunyaev 2003; Sunyaev et al. 2003). That is, we have information about:

(i) surface brightness in lines (Fig. 2, left-hand panel), i.e. $I(x, y) \propto \int n_e^2(x, y, z)dz$ if one assumes isothermal galaxy cluster (effects of non-constant temperature and abundance of elements are discussed in Section 6).

(ii) emissivity-weighted projected velocity (Fig. 2, middle panel)

$V_{2D}(x, y) = \frac{\int V(x, y, z)n_e(x, y, z)dz}{\int n_e(x, y, z)dz}$

(in practice measured projected velocity is averaged over some finite solid angle; see Section 5).

(iii) emissivity-weighted velocity dispersion (Fig. 2, right panel)

$\sigma(x, y) = \sqrt{(V^2(x, y, z))_c - (V(x, y, z))^2_c} = \sqrt{(V^2(x, y, z))_c - V_{2D}(x, y)}$.

where $n_e$ denotes the number electron density and $V$ is a velocity component along the line of sight. Here $\langle \rangle_c$ denotes emissivity-weighted averaging along the line of sight, which we assume to be along $z$ direction.

Relation between the PS of the 3D velocity field, the 2D projected velocity and the velocity dispersion for a line of sight with projected coordinates $(x, y)$ is as follows:

$\langle |V_{2D}(k_x, k_y, k)\rangle^2 = \int P_{3D}(k_x, k_y, k_z)P_{EM}(k_x, x, y)dk_z$ (4)

and

$\langle \sigma^2(x, y) \rangle = \int P_{3D}(k_x, k_y, k_z)(1 - P_{EM}(k_x, x, y))dk_z, dk_y, dk_x$ (5)

where $\langle \rangle$ is the ensemble averaging over a number of realizations, $\langle |V_{2D}(k_x, k_y, k)\rangle^2$ is an expectation value of the 2D PS of the observed projected velocity field $V(x, y)$, $P_{3D}$ is the PS of the 3D velocity field and $P_{EM}$ is the PS of normalized emissivity distribution along the line of sight. For more details, see Appendixes A and B.

In Fig. 3 we illustrate equation (5) for a simple spherically symmetric $\beta$-model of galaxy cluster with core radius $r_c = 10$ kpc and $\beta = 0.6$. 3D velocity PS has a cored power-law model (equation 2), i.e. is flat on $k < k_m = 0.005$ kpc$^{-1}$ and has a Kolmogorov slope $\alpha = -11/3$. Observed velocity dispersion averaged over 100 realizations is shown with dots; the error bars show the expected uncertainty in one measurement. The right-hand side of equation (5) is shown in red. Minor difference between two curves at small $R$ is due to finite resolution of simulations.

Once we construct the map of projected velocity $V_{2D}(x, y)$, one can also find rms velocity of the 2D field at each distance $r$ from the cluster centre as

$V_{rms}(r) = \sqrt{(V_{2D}(x, y))^2_r - (V_{2D}(x, y))^2}$

where $\langle V_{2D}(x, y) \rangle$ denotes mean velocity in ring at distance $r$ from the centre. Below we use the observed velocity dispersion and rms of the projected velocity field to constrain the power spectrum.

4 STRUCTURE FUNCTION AND OBSERVED VELOCITY DISPERSION

Often a SF of the velocity field is used instead of the power spectrum, which is defined as

$\text{SF} = \langle (V(x + \Delta x) - V(x))^2 \rangle$

where $\Delta x = 100$ kpc. 

Figure 2. Maps of observables. Left: surface brightness in line (arbitrary units); middle: emissivity-weighted projected velocity field in km s$^{-1}$ (centroid shift of the line); right: velocity dispersion in km s$^{-1}$ (line broadening). Here, we consider only the velocity component along the line of sight. We assume $\beta$-model of the emissivity with $\beta = 0.6$ and $r_c = 10$ kpc and a random, uniform and homogeneous Gaussian velocity field with cored power-law 3D power spectrum (equation C1) with $k_m = 0.005$ kpc$^{-1}$ and Kolmogorov slope $\alpha = -11/3$ (see Section 2). The size of each map is $1 \times 1$ Mpc.
where averaging is over a number of pairs of points in space separated by distance $\Delta x$. The line-of-sight velocity dispersion can be linked to the SF. Indeed, since the emissivity peaks at the centre of the cluster and declines with the radius, the largest contribution to the total flux and to the line-of-sight velocity dispersion at distance $R$ from the centre comes from the region, the size of which is $\propto R$.

The SF and the observed velocity dispersion can be related to the PS (see appendices C and D):

$$\text{SF}(x) = 2 \int_{-\infty}^{\infty} P_{1D}(k) (1 - \cos 2\pi k \Delta x) \, dk,$$

and

$$\langle \sigma^2(R) \rangle = \int_{-\infty}^{\infty} P_{1D}(k) (1 - P_{EM}(k)) \, dk,$$

where $P_{1D}$ is an expectation value of the 1D velocity PS and $P_{EM}$ is a PS of normalized emissivity along the line of sight. Fig. 4 shows the integrands in equations (8) and (9) multiplied by $k$ and $2k$, respectively, for the line of sight near the cluster centre (black curves) and at a projected distance $R = 800$ kpc from the centre (red curves). Extra factor of 2 for $\sigma^2(R)$ is introduced to compensate for the factor of 2 in front of the expression (8) for the SF. It is more clear if one considers the limits of these equations at large $x$ and $R$. When $x \to \infty$ the emissivity distribution is very broad and $P_{EM}$ is almost a $\delta$-function. Therefore,

$$\lim_{x \to \infty} \text{SF}(x) = 2 \int_{-\infty}^{\infty} P_{1D}(k) \, dk ,$$

and

$$\lim_{R \to \infty} \langle \sigma^2(R) \rangle = \int_{-\infty}^{\infty} P_{1D}(k) \, dk .$$

From Fig. 4, it is clear that the integrands in equations (8) and (9) are very similar, suggesting that observed $2\sigma^2(R)$ should correlate well with the SF.

The SF and the velocity dispersion (equations C5 and D1, respectively) are plotted in Fig. 6 in left-hand panel. We fixed parameters of the $\beta$-model of the cluster and varied the slope $\alpha$ and break $k_m$ of the power spectrum model (equation 2). The relation of SF and $2\sigma^2$ is shown in the left-bottom panel in Fig. 6. For a given $R$, $2\sigma^2$ is used for $x$-axis, while the SF is plotted as a function of $l_{eff}(R)$, where $l_{eff}$ is an effective length along the line of sight, which provides dominant contribution to the line flux. $l_{eff}$ is found from the condition that

$$\int_{l_{eff}}^{\infty} n_0^2 (\sqrt{R^2 + l^2}) \, dl / \int_{0}^{\infty} n_0^2 (\sqrt{R^2 + l^2}) \, dl \approx 0.5.$$

Relation between $l_{eff}$ and projected distance depends on the $\beta$-model of galaxy cluster as shown in Fig. 5.

We then made multiple statistical realizations of the PS for a simple $\beta$-model of galaxy cluster with $\beta = 0.6$ and $r_c = 10$ kpc to estimate the uncertainties. The size of the box is 1 Mpc and resolution is 2 kpc. We assume that the 3D PS of the velocity field has a cored power-law model (equation C1) with slope $\alpha$ and break wavelength (injection scale) at $k_m$. We made 100 realizations of a Gaussian field with random phases and Gaussian-distributed amplitudes in Fourier space. Taking inverse Fourier transform, we calculated one component of the 3D velocity field (component along the line of
Dependence of the effective length along the line of sight $l_{\text{eff}}(R)$ (equation 12) on the projected distance $R$ for different $\beta$-models of galaxy clusters.

The contribution of the second term to the integral is small since $P_{\text{SH}}(k_x,k_y)$ is a PS of a mask, where the mask is defined as zero outside and unity inside the region, from which the spectrum is extracted (see Appendix E for details). Velocity dispersion (i.e. the line broadening) measured from the same region is

$$\langle \sigma^2 \rangle = \int P_{3D}(k_x,k_y,k_z)(1 - P_{\text{EM}}(k_x,k_y)) \, dk, \quad (13)$$

Therefore the ratio $V_{\text{rms}}^2/\langle \sigma^2 \rangle$ is

$$\frac{V_{\text{rms}}^2}{\langle \sigma^2 \rangle} = \int \frac{P_{3D}(k_x,k_y,k_z)P_{\text{EM}}(k_x,k_y)\,dk}{P_{3D}(k_x,k_y,k_z)(1 - P_{\text{EM}}(k_x,k_y)) \, dk} \quad (15)$$

which can be used as an additional proxy of the length scales of gas motions. This ratio is mostly sensitive to the break of the cored power-law model of the PS $P_{\text{eff}}$. Basically at a given line of sight, which is characterized by an effective length $l_{\text{eff}}$, the small-scale motions (i.e. $k > 1/l_{\text{eff}}$) are mostly contributing to line broadening, while larger scale motions predominantly contribute to the rms of the projected velocity field.

Fig. 7 shows the ratio $V_{\text{rms}}^2/\langle \sigma^2 \rangle$ and its uncertainty calculated for different values of parameter $k_{\text{m}}$, $V_{\text{rms}}$ and $\sigma$ are averaged over rings at distance $R$ from the cluster centre. Clearly, if $k_{\text{m}}$ is large, then all motions are on small scales and the ratio is small. The larger is the $k_{\text{m}}$, the more power is at large scales and the larger is the $V_{\text{rms}}$. The larger is the injection scale, the stronger is the increase of the ratio with distance and the more prominent is the peak (see Fig. 7). Here we assume that the full map of projected velocity field is available. Clearly, the uncertainties will increase if the data are available for several lines of sight, rather than for the full map.

Looking at equation (15) it is easy to predict the behaviour of the ratio on small and large projected distances $R$. Let us specify the shape of area, namely assume that we measure velocity in circles with radius $R$ around the cluster centre. When $R \to 0$ then the region is very small and $P_{\text{SH}}(k_x,k_y) \to 1$ over broad range of wavenumbers $k < 1/R$ and the ratio $V_{\text{rms}}^2/\langle \sigma^2 \rangle \to 0$. At large $R$ $P_{\text{SH}}(k_x,k_y) \to 0$ and $P_{\text{EM}}(k_x,k_y)$ [since $n_2(z)$ distribution along the line of sight on large $R$ is broad], equation (15) becomes

$$\frac{V_{\text{rms}}^2}{\langle \sigma^2 \rangle} = \frac{\int P_{3D}(k_x,k_y,k_z)P_{\text{EM}}(k_z) \, dk}{\int P_{3D} \, dk} \quad (16)$$

and it is a decreasing function of $R$.

The sensitivity of ratio $V_{\text{rms}}^2/\langle \sigma^2 \rangle$ to the slope of the power spectrum is modest. There are only changes in normalization, but the overall shape is the same.

6 RECOVERING 3D VELOCITY POWER SPECTRUM FROM 2D PROJECTED VELOCITY FIELD

Mapping of the projected velocity field $V_{\text{2D}}(x,y)$ provides the most direct way of estimating the 3D velocity field PS. The 2D and 3D PS are related according to equation (4), which we re-write as

$$P_{\text{2D}}(k) = \int P_{\text{3D}}(k_x,k_y,k_z)P_{\text{EM}}(k_x,k_y) \, dk_z, \quad (17)$$

where $k = \sqrt{k_x^2 + k_y^2}$. This equation can be written as

$$P_{\text{2D}}(k) = \int_0^{1/l_{\text{eff}}} P_{\text{3D}}(\sqrt{k_x^2 + k_y^2})P_{\text{EM}}(k_x,k_y) \, dk_z + \int_{1/l_{\text{eff}}}^{\infty} P_{\text{3D}}(\sqrt{k_x^2 + k_y^2})P_{\text{EM}}(k_x,k_y) \, dk_z \quad (18)$$

The contribution of the second term to the integral is small since $P_{\text{EM}}(k_x,k_y) \to 0$ on $k > 1/l_{\text{eff}}$. In the limit of $k \gg 1/l_{\text{eff}}$ (at a given projected distance) the expression reduces to

$$P_{\text{2D}}(k) \approx P_{\text{3D}}(k) \int P_{\text{EM}}(k_x,k_y) \, dk_z, \quad (19)$$

i.e. 2D PS is essentially equal to the 3D PS of the velocity field apart from the normalization constant $\int P_{\text{EM}}(k_x,k_y) \, dk_z$, which is easily measured for a cluster. We show below that this simple relation (19) provides an excellent approximation for full expression (17) for a Coma-like clusters with flat surface brightness core.

Monthly Notices of the Royal Astronomical Society © 2012 RAS
Figure 6. Left-hand panel: SF (see analytical expression C5), line-of-sight velocity dispersion multiplied by a factor of 2 (equations D1 and D5) and their relation for different models of cored power-law power spectrum (equation C1). Parameters of the power spectrum (slope and break wavenumber) are shown in the top left corner. Parameters of the $\beta$-model are given in the bottom right corner. Right-hand panel: the same as left-hand panel, but calculated by averaging over 100 statistical realizations of velocity field. The uncertainties in single measurement of the velocity dispersion are shown with dotted curves. The choice of parameters is discussed in Section 2.

For peaked clusters (cool core) $P_{3D}/P_{2D}$ depends on projected distance from the cluster centre since $l_{\text{eff}}$ changes significantly with distance.

It is convenient to use characteristic scale-dependent amplitudes of the velocity field variations, rather than the PS. The amplitude for 3D and 2D spectra is defined as

$$A_{3D}(k) = \sqrt{P_{3D}(k)4\pi k^3} \quad (20)$$

$$A_{2D}(k) = \sqrt{P_{2D}(k)2\pi k^2}. \quad (21)$$
Velocity dispersion and $V_{\text{rms}}$ as functions of distance from the cluster centre with uncertainties due to the stochastic nature of the velocity field (left panels) and their ratio from equation (15) (right-hand panel). $V_{\text{rms}}(R)$ and $\sigma(R)$ are averaged over a ring at distance $R$ from the cluster centre. Errors show the characteristic uncertainties in one measurement. The slope of assumed velocity PS is $-11/3$. Break wavenumber $k_m$ of the PS is shown on the right-hand panel. Colour coding is the same in both panels.

In these notations the relation (19) between PS transforms to

$$A_{2D}(k) = A_{3D}(k) \sqrt{\frac{1}{2} \int \frac{P_{3D}(k, x, y) \, dk}{k}}. \tag{22}$$

Integral $\int P_{3D}(k, x, y) \, dk$, can be estimated as $\frac{1}{l_{\text{eff}}}$, since the largest contribution is on $k < 1/l_{\text{eff}}$. Equation (22) becomes

$$A_{2D}(k) = A_{3D}(k) \sqrt{\frac{1}{2} k_{\text{eff}}}. \tag{23}$$

The essence of this relation is that the amplitude of the 3D velocity fluctuations is attenuated in the 2D projected velocity field by a factor of order $\sqrt{\frac{l_{\text{eff}}}{N_{\text{edd}}}}$, where $N_{\text{edd}}$ is the number of independent eddies which fit into effective length along the line of sight.

We illustrate the above relation for the case of the Coma cluster. The density distribution in the Coma can be characterized by a $\beta$-model with $\beta = 0.6$ and co-radius $r_c = 245$ kpc. In Fig. 8 we plot the ratio $A_{2D}(k)/A_{3D}(k)$ evaluated using equations (19) and (17) for a number of 3D PS models calculated at two projected distances from the Coma centre. One can see that on spatial scales of less than 1 Mpc, equation (22) is fully sufficient. The variations of the relation for different projection distances (projected distances from 0 to 300 kpc were used) affect only the normalization of the relation and can easily be accounted for.

With Astro-H the 2D velocity field in the Coma can be mapped with the $\sim 1.7$ arcmin resolution, which corresponds to $\sim 46$ kpc. Mapping $450 \times 450$ kpc central region of the Coma would require about 36 pointings. For practical reasons it may be more feasible to make a sparse map (e.g. two perpendicular stripes) to evaluate $A_{2D}$ (e.g. computing correlation function or using a method described in Arévalo et al. 2012).

7 DISCUSSION

7.1 Limiting cases of small- and large-scale motions

Measuring characteristic amplitude of mean velocity ($V_{\text{rms}}$) and velocity dispersion ($\sigma$) we can distinguish whether the turbulence is dominated by small- or large-scale motions. Clearly, the motions on scales much smaller than the effective length along the line of sight near the cluster centre can only contribute to the line broadening. This sets the characteristic value of the lowest spatial scale which can be measured. The largest measurable scale is set by the maximum distance $R_{\text{max}}$ from the cluster centre where the line parameters can be accurately measured without prohibitively long exposure time. Thus, the range of scales $l$, which can be probed with these measurements, is $l_{\text{eff}}(R = 0) < l < R_{\text{max}}$. The crucial issue in the measurements is 'sample variance' of measured quantities caused by the stochastic nature of turbulence. We can expect two limiting cases (see Fig. 7).

1) Small-scale motions

In case of small-scale motions $l \ll l_{\text{eff}}(R = 0)$ [i.e. $k_m \gg k_{\text{eff}}(R = 0)$] one expects $\sigma(R)$ to be independent of radius and $V_{\text{rms}}(R) \ll \sigma(R)$. $\sigma(R)$ is expected to have low sample variance and can be measured accurately even for a single line of sight, provided sufficient exposure time. Measurements of $V_{\text{rms}}(R)$ are strongly affected by sample variance and depend on the geometry of the measured map of the projected velocity dispersion $V(x, y)$. If $V(x, y)$ is measured only at two positions, then the uncertainty in $V_{\text{rms}}(R)$ is of the order of its value and the ratio $\sigma(R)/V_{\text{rms}}(R)$ gives only low limit on $k_m$. We note that in this limit of small-scale motions the assumption of a uniform and homogeneous Gaussian field can be relaxed and measured values of line broadening $\sigma$ simply reflect the total variance of the velocity along the given line of sight, while the possibility of determining the spatial scales of motions are limited. Variations of $\sigma$ with radius will simply reflect the change of the characteristic velocity amplitude.

Figure 7. Velocity dispersion and $V_{\text{rms}}$ as functions of distance from the cluster centre with uncertainties due to the stochastic nature of the velocity field (left panels) and their ratio from equation (15) (right-hand panel). $V_{\text{rms}}(R)$ and $\sigma(R)$ are averaged over a ring at distance $R$ from the cluster centre. Errors show the characteristic uncertainties in one measurement. The slope of assumed velocity PS is $-11/3$. Break wavenumber $k_m$ of the PS is shown on the right-hand panel. Colour coding is the same in both panels.
...and modified at large distances according to $\sigma_{\text{eff}} = k_T R$ and varying total rms of the velocity field in one dimension. The model of the Perseus cluster was taken from Churazov et al. (2004) and modified at large distances according to Suzaku observations at the edge of the cluster (Simionescu et al. 2011), i.e. the electron number density is

$$N_e(r) = 4.68 \times 10^{-2} \left[ 1 + \left( \frac{r}{5000} \right)^8 \right] + 4.86 \times 10^{-3} \left[ 1 + \left( \frac{r}{5000} \right)^{0.8} \right]$$

and the temperature profile is

$$T(r) = 7 \frac{1}{2.3 + \left( \frac{r}{5000} \right)^2} \times \left( 1 + \frac{r}{5000} \right)^{-1}.$$  

We assume that the abundance of heavy elements is constant and is equal to 0.5 relative to solar (Anders & Grevesse 1989). Fig. 9 shows the calculated width of 6.7 keV line assuming various 1D rms velocities. Thermal broadening is shown with the dashed magenta curve. One can see that thermal broadening starts to dominate broadening due to motions only if $V_{\text{rms}} < 150$ km s$^{-1}$. However, the lack of resonant scattering signatures in the spectrum of the Perseus cluster suggests that the expected velocity is higher than 400 km s$^{-1}$ in the centre of the Perseus cluster (Churazov et al. 2004). Astro-H will have energy resolution of 7 eV at 6.7 keV, therefore broadening due to gas motions with $V_{\text{rms}} \propto 400$ km s$^{-1}$ will be easy to observe (Fig. 9) in the Perseus cluster.

Figure 9. Width of the line of He-like iron line at 6.7 keV in Perseus cluster, assuming different 1D rms velocities. FWHM is related with the width as $\text{FWHM} = 1.66 \Delta E$. Solid curves show broadening due to gas motions only; the dashed curve shows the thermal broadening. Here we assumed the cored power-law 3D power spectrum with $\alpha = -11/3$ and $k_0 = 0.001$ kpc$^{-1}$.
7.3 The effect of radial variations of the gas temperature and metallicity

The analysis described in the previous sections was done assuming an isothermal $\beta$-model spherically symmetric cluster with emissivity simply $\propto n_\text{e}^2$. Clearly, real clusters are more complicated, even if we keep the assumption of spherical symmetry. First of all the gas temperature and metallicity often vary with radius. These variations will be reflected in the weighting function $n_\text{e}^2(\sqrt{R^2 + z^2})$, which relates 3D velocity field and observables. To verify how strongly these assumptions affect the results, we calculated velocity dispersion assuming detailed model of the Perseus cluster (see above). We assumed constant abundance profile and more realistic peaked abundance profile, taken from Suzaku (Simionescu et al. 2011) and Chandra/XMM observations

$$Z(r) = 0.4 \frac{2.2 + (\frac{r}{s})^2}{1 + (\frac{r}{s})^2}. \quad (27)$$

We calculated the emissivity of the He-like iron line at 6.7 keV and used this emissivity as a weighting function for the calculation of the expected projected velocity and velocity dispersion. Fig. 10 shows the velocity dispersion along one line of sight calculated for the most simple model of emissivity and assuming more complicated models described above. One can see that mean value and uncertainties are very similar in all cases. Clearly that averaging velocity dispersion over a ring will decrease the uncertainty in one measurement (Fig. 10, black dashed curve).

7.4 Influence of density fluctuations

The hot gas density in galaxy clusters is strongly peaked towards the centre. However, besides the main trend, there are density fluctuations, which could contribute to the observed fluctuations of the projected velocity. Let us split the density field in two components $n = n_0 + \delta n$,

$$V_{2D}(x, y) = \int n_0(z)V(x, y, z)\,dz + 2\int n_0(z)\delta nV(x, y, z)\,dz, \quad (29)$$

where $n_0$ corresponds to the smooth global profile and $\delta n$ represents fluctuating part. Neglecting terms of the order $(\delta n)^2$, the emissivity-weighted projected velocity is

The analysis of X-ray surface brightness fluctuations in the Coma cluster (e.g. Churazov et al. 2012) has shown that the amplitude of the density fluctuations $(\frac{\delta n}{n_0})$ is of the order of $\sim 2$--$10$ per cent. Assuming that the same number is applicable to other clusters, the second term in equation (29) is small and the contribution of the density fluctuation to projected velocity can be neglected.

7.5 Measurement requirements

To illustrate the most basic requirements for the instruments to measure the ICM velocity field, let us consider two examples of a rich cluster and an individual elliptical galaxy, representing the low temperature end of the cluster-group-galaxy sequence:

(i) Perseus cluster, $T_{\text{mean}} = 5$ keV, line of Fe XXV at 6.7 keV, distance 72 Mpc.

(ii) Elliptical galaxy NGC 5813, $T_{\text{mean}} = 0.65$ keV, line of O VIII at 0.654 keV, distance 32.2 Mpc.

Table 1 shows the FWHM of these lines calculated if only thermal broadening is taken into account, shift of the line energy in the case of gas motions with $V = c_\text{s}$ and desirable angular resolution of the instrument. Future X-ray missions, such as Astro-H and ATHENA, will have energy resolution $\sim 5$ eV and $\sim 3$ eV, respectively. Such energy resolution is sufficient to measure broadening of lines in hot systems like galaxy clusters. Cold systems, like elliptical galaxies, require even better energy resolution. However, turbulence can still be measures using the resonant scattering effect (see e.g. Werner et al. 2009; Zhuravleva et al. 2011) or by using gratings spectrometer observations. Angular resolution of $\sim 1$ arcmin for nearby galaxy clusters should be sufficient to study the most basic characteristics of the ICM velocity field, while for elliptical galaxies the resolution at the level of $\sim $ arcsec (comparable with Chandra resolution) would be needed.

Astro-H observatory will have energy resolution $\sim 5$ eV, field of view 2.85 arcmin and angular resolution 1.7 arcmin, which means that it will be possible to measure shift and broadening of lines as a function of projected distance from the centre in nearby clusters. For example if one assumes that rms velocity of gas motions in Perseus cluster is $\sim 300$ km s$^{-1}$, then $\sim 4 \times 10^5$ s is enough to measure profiles of mean velocity and velocity dispersion with a statistical uncertainty of $\sim 30$ km s$^{-1}$ (90 per cent confidence) in a stripe $\pm 200$ kpc (seven independent pointing and 28 independent measurements in $1.4 \times 1.4$ arcmin$^2$ pixels) centred in the centre of

Table 1. Energy and angular resolutions requirements for future X-ray observatories.

| Cluster            | Energy line | Angular resolution |
|--------------------|-------------|--------------------|
| Perseus cluster    | Fe xxv line | 0.5 arcmin         |
| NGC 5813           | O VIII line | 2 arcsec           |

Monthly Notices of the Royal Astronomical Society © 2012 RAS
I. Zhuravleva et al.

the cluster. In order to measure velocity with the same accuracy at larger distances from the centre, e.g. at 500 kpc and 1 Mpc, one would need $8 \times 10^5$ s and $4 \times 10^6$ s exposure, respectively.

8 CONCLUSIONS

Various methods of constraining the velocity power spectrum through the observed shift of line centroid and line broadening are discussed.

(i) Changes of the line broadening with projected distance reflect the increase of the spread in the velocities with distance, closely resembling the behaviour of the SF of the velocity field.

(ii) Another useful quantity is the ratio of the characteristic amplitude of the projected velocity field to the line broadening. Since the projected velocity field mainly depends on large-scale motions, while the line broadening is more sensitive to small-scale motions, this ratio is useful diagnostics of the shape of the 3D velocity field power spectrum.

(iii) Projected 2D velocity field power spectrum can be easily converted into 3D power spectrum. This conversion is especially simple for cluster with an extended flat core in the surface brightness (like Coma cluster).

Analytical expressions are derived for a $\beta$-model clusters, assuming homogeneous isotropic Gaussian 3D velocity field. The importance of the sample variance, caused by the stochastic nature of the turbulence, for the observables is emphasized.

ACKNOWLEDGMENTS

IZ, EC and AK would like to thank Kavli Institute for Theoretical Physics (KITP) in Santa Barbara for hospitality during workshop ‘Galaxy clusters: crossroads of astrophysics and cosmology’ in 2011 March–April, where part of the work presented here was carried out. This research was supported in part by the National Science Foundation under Grant No. NSF PHY05-51164 and by the Division of Physical Sciences of the RAS (the program “Extended Objects in the Universe”, OFN-16). IZ would like to thank the International Max Planck Research School on Astrophysics (IMPRS) in Garching.

APPENDIX A: 3D VELOCITY POWER SPECTRUM AND PROJECTED VELOCITY FIELD

Let us assume that the line-of-sight component of the 3D velocity field \( \mathbf{V}_{3D}(x, y, z) \) is described by a Gaussian (isotropic and homogeneous) random field. We assume that the centroid shift and the width of lines contain most essential information on the velocity field. Here and below we adopt the relation \( k = 1/r \) without factor \( 2\pi \) (see Section 2 for details).

Projected 2D velocity along the line of sight (observed centroid shift of the emission line) in \( z \) direction is

\[
V_{2D}(x, y) = \frac{\int V_{3D}(x, y, z) n_s(x, y, z) \, dz}{\int n_s^2(x, y, z) \, dz},
\]

(A1)

where \( V_{3D} \) is the \( z \) component of the 3D velocity field and \( n_s \) is the electron number density. Denoting normalized emissivity along the line of sight at a certain position with coordinates \((x, y)\) as \( \epsilon(z) = n_s^2(x, y, z) / \int n_s^2(x, y, z) \, dz \) the previous relation can be re-written as

\[
V_{2D}(x, y) = \int V_{3D}(x, y, z) \epsilon(z) \, dz.
\]

(A2)

Applying the convolution theorem one can find the Fourier transform of \( V_{3D}(x, y, z) \epsilon(z) \) as

\[
\hat{V}_{2D}(k_x, k_y) = \int \hat{V}_{3D}(k_x, k_y, k_z) \epsilon(k_z) \, dk_z,
\]

(A3)

where \( \hat{V}_{3D} \) and \( \epsilon \) are Fourier transforms of the 3D velocity field and normalized emissivity, respectively. The projection-slice theorem states that

\[
\hat{f}_{2D}(k_x, k_y) = \hat{f}_{3D}(k_x, k_y, 0).
\]

(A4)

Accounting for (A3) and (A4) we can write the Fourier transform of 2D velocity field as

\[
\hat{V}_{2D}(k_x, k_y) = \int \hat{V}_{3D}(k_x, k_y, k_z) \epsilon^*(k_z) \, dk_z,
\]

(A5)

where * denotes conjugation.

Averaging over a number of realization we find the power spectrum of the projected mean velocity

\[
\langle |\hat{V}_{2D}(k_x, k_y)|^2 \rangle = \left( \int \left| \hat{V}_{3D}(k_x, k_y, k_z) \epsilon^*(k_z) \right|^2 \, dk_z \right)^2.
\]

(A6)

The right part of the equation above can be re-written as

\[
\int (\hat{V}_{3D}(k_x, k_y, k_z) \hat{V}_{3D}^*(k_x, k_y, k_z)) \epsilon^*(k_z) \epsilon(k_z) \, dk_z \, dk_{z'}.
\]

(A7)

Since phases are random, all cross terms after averaging over a number of realizations will give 0 if \( k_z \neq k_{z'} \). Therefore,

\[
\langle |\hat{V}_{2D}(k_x, k_y)|^2 \rangle = \int |\hat{V}_{3D}(k_x, k_y, k_z) \epsilon^*(k_z) |^2 \, dk_z.
\]

(A8)

Denoting power spectra of the 3D velocity field and normalized emissivity as \( P_{3D} \) and \( P_{EM} \), respectively, the final expression is

\[
\langle |\hat{V}_{2D}(k_x, k_y)|^2 \rangle = \int P_{3D}(k_x, k_y, k_z) P_{EM}(k_z) \, dk_z.
\]

(A9)

APPENDIX B: 3D VELOCITY POWER SPECTRUM AND PROJECTED VELOCITY DISPERSION

Projected mean velocity dispersion for the line of sight with coordinates \((x, y)\) averaged over a number of realization is defined as

\[
\langle \sigma^2(x, y) \rangle = \left( \int V_{3D}^2(x, y, z) \epsilon(z) \, dz \right) - \left( \int V_{3D}(x, y, z) \epsilon(z) \, dz \right)^2.
\]

(B1)

It can be re-written as

\[
\langle \sigma^2(x, y) \rangle = \int \left( \langle V_{3D}^2(x, y, z) \rangle \epsilon(z) - \langle V_{3D}^2(x, y) \rangle \right) \, dz.
\]

(B2)

Expanding \( V_{3D} \) and \( V_{3D}^2 \) through the Fourier series, averaging over realizations and keeping non-zero cross terms will give

\[
\langle \sigma^2(x, y) \rangle = \int |\hat{V}_{3D}(k_x, k_y, k_z)|^2 \, dk_x \, dk_y \, dk_z \int \epsilon(z) \, dz
\]

\[
- \int \left| \hat{V}_{2D}(k_x, k_y) \right|^2 \, dk_x \, dk_y.
\]

(B3)

Since emissivity along the line of sight is normalized so that \( \int \epsilon(z) \, dz = 1 \) and accounting for equation (A9) the final expression for projected velocity dispersion will be

\[
\langle \sigma^2(x, y) \rangle = \int P_{3D}(k_x, k_y, k_z) (1 - P_{EM}(k_z)) \, dk_x \, dk_y \, dk_z.
\]

(B4)

APPENDIX C: RELATION BETWEEN STRUCTURE FUNCTION AND CORED POWER-LAW 3D POWER SPECTRUM

Let us assume 3D isotropic and homogeneous PS of the velocity field is described as

\[
P_{3D}(k_x, k_y, k_z) = \frac{B}{\left( 1 + \frac{k_a^2 + k_{\beta}^2}{k_{m}^2} \right)^{\alpha/2 + 1}}.
\]

(C1)

where \( k_m \) is a wavenumber at which \( \beta \)-model has a break (e.g. an injection scale in turbulence model), \( \alpha \) is a slope of PS on \( k > k_m \) and \( B \) is PS normalization, which is defined so that the characteristic amplitude \( A \) of velocity fluctuations at \( k_{ref} \) is fixed, i.e.

\[
B = \frac{A^2}{4\pi k_{ref}^2 P_{3D}(k_{ref})}.
\]

(C2)

Integrating C1 over \( dk_x \, dk_y \) we find 1D PS

\[
P_{1D}(k) = \frac{2\pi B k_a^2 \left( 1 + \frac{k_m^2}{k_a^2} \right)^{1/2 + \frac{\alpha}{2}}} {\alpha - 2}.
\]

(C3)

SF is related to 1D PS by the transformation (Rytov, Kravtsov & Tatarskii 1988)

\[
SF(x) = 2 \int_{-\infty}^{+\infty} P_{1D}(k) (1 - \cos 2\pi k_a x) \, dk_a.
\]

(C4)

Substituting (C3) with (C4) and assuming \( \alpha > 3 \) yield

\[
SF(x) = \frac{4 B k_m^2}{(2\pi \xi)^{1/2}} \left( \pi^{1/2} \Gamma(\xi) - 2\pi \xi^{1/2} K_\xi (\xi, 2\pi x k_m) \right),
\]

(C5)

where \( \xi = \frac{\alpha - 3}{2} \) and \( K_\xi \) is a modified Bessel function of the second kind.
APPENDIX D: RELATION BETWEEN VELOCITY DISPERSION ALONG THE LINE OF SIGHT AND POWER SPECTRUM

$P_{1D}$ and $P_{3D}$ are related as $P_{1D}(k_z) = \int P_{3D}(k_x, k_y, k_z) dk_x dk_y$, therefore equation (B4) can be re-written as

$$\langle \sigma^2(R) \rangle = \int_{-\infty}^{\infty} P_{1D}(k_z)(1 - P_{EM}(k_z)) dk_z,$$  \hspace{1cm} (D1)

where $R$ is projected distance from the centre.

If electron number density is described by $\beta$-model with normalization $n_0$ and core radius $R_c$

$$n_e(r) = \frac{n_0}{\left(1 + \frac{r^2}{(R_c)^2}\right)^2},$$  \hspace{1cm} (D2)

then the emissivity is

$$\epsilon(r) = \frac{R_{\beta}^3 r^2}{(C + c^2 r^2)^{3}},$$  \hspace{1cm} (D3)

where $r^2 = R^2 + z^2$, $C = R^2 + R^2$ and we assume normalization $n_0 = 1$. The Fourier transform of emissivity is

$$\hat{\epsilon}(k_z) = \int_{-\infty}^{\infty} \frac{R_{\beta}^3}{(C + x^2)^{3/2}} \cos(2\pi k_z x) dx,$$  \hspace{1cm} (D4)

where terms with $i \sin(2\pi k_z z)$ are zero since integrand is symmetrical. Dividing (D4) by the total flux and assuming $\beta > 1/6$ one can find weight $W(k_z)$ as

$$W(k_z) = \frac{2C^2 k_z^2 \pi^2 K_\alpha(-\pi, 2\sqrt{C} k_z \pi)}{\Gamma(\pi)},$$  \hspace{1cm} (D5)

where $\alpha = 3\beta - \frac{1}{2}$ and $K_\alpha$ is a modified Bessel function of the second kind.

APPENDIX E: RATIO OF OBSERVED RMS VELOCITY TO OBSERVED VELOCITY DISPERSION

Let us assume that spectrum is extracted from the region with the area $\int_{\text{shape}} dx dy$. The rms velocity from this spectrum averaged over a number of realizations is

$$\langle V_{\text{rms}}^2 \rangle = \left< \frac{\int_{\text{shape}} V_{3D}(x, y) dx dy}{\int_{\text{shape}} dx dy} \right> \left< \frac{\int_{\text{shape}} V_{3D}(x, y) dx dy}{\int_{\text{shape}} dx dy} \right>,$$  \hspace{1cm} (E1)

where $<>$ denotes averaging over realizations. Accounting for equation (A2) we can re-write the first term in the above equation as

$$\left< \frac{\int_{\text{shape}} \left( \int V_{3D}(x, y, z)\epsilon(z) dz \right)^2 dx dy}{\int_{\text{shape}} dx dy} \right> = \frac{1}{\int_{\text{shape}} dx dy} \int_{\text{shape}} \left( \int V_{3D}(x, y, z)\epsilon(z) dz \right)^2 dx dy$$

$$= \frac{1}{\int_{\text{shape}} dx dy} \int_{\text{shape}} \left( \int V_{3D}(k_{x}, k_{y}, k_{z})e^{i2\pi k_{x}x}e^{i2\pi k_{y}y} \times F_{EM}(k_{z}) \right) \times \left( \int V_{3D}(k_{x}, k_{y}, k_{z})e^{i2\pi k_{x}x}e^{i2\pi k_{y}y} F_{EM}(k_{z}) \right) \times d^3 k d^3 k d^3 k,$$  \hspace{1cm} (E2)

where $F_{EM}$ is a Fourier transform of emissivity along the line of sight. Averaging over a number of realizations will leave non-zero terms only if $k_x = k_y$. Therefore, the first term in equation (E1) is

$$\int_{\text{shape}} \int P_{3D}(k_x, k_y, k_z) P_{EM}(k_z) d^3 k \ dx \ dy$$

$$= \int P_{3D}(k_x, k_y, k_z) P_{EM}(k_z) \ dx \ dy \ dy \ dy,$$  \hspace{1cm} (E3)

The second term in equation (E1) can be written as

$$\left< \frac{\int_{\text{shape}} \left( \int V_{3D}(x, y, z)\epsilon(z) dz \right)^2 dx dy}{\int_{\text{shape}} dx dy} \right> = \left< \frac{\int_{\text{shape}} \left( \int V_{3D}(k_x, k_y, k_z) e^{i2\pi k_{x}x} e^{i2\pi k_{y}y} F_{EM}(k_{z}) d^3 k \ dx \ dy \ dy \ dy \right)^2}{\int_{\text{shape}} \ dx \ dy} \right>.$$  \hspace{1cm} (E4)

Squaring and averaging over realizations yield

$$\frac{1}{\int_{\text{shape}} dx dy} \int_{\text{shape}} \left( \int_{\text{shape}} \left( \int V_{3D}(x, y, z)\epsilon(z) dz \right)^2 dx dy \right) \times \int_{\text{shape}} \left( \int V_{3D}(x, y, z)\epsilon(z) dz \right)^2 dx dy \ dy \ dy \ dy,$$  \hspace{1cm} (E5)

or

$$\frac{1}{\int_{\text{shape}} dx dy} \int_{\text{shape}} \left( \int_{\text{shape}} \left( \int V_{3D}(x, y, z)\epsilon(z) dz \right)^2 dx dy \right)^2 \times \int_{\text{shape}} \left( \int V_{3D}(x, y, z)\epsilon(z) dz \right)^2 dx dy \ dy \ dy \ dy,$$  \hspace{1cm} (E6)

where $S(x, y)$ is a mask, which is zero outside and unity inside the area, from which spectrum is extracted. Denoting power spectrum of $S(x, y)/(\int_{\text{shape}} dx \ dy)^2$ as $P_{SH}(k_x, k_y)$, the second term in equation (E1) becomes

$$\int P_{3D}(k_x, k_y, k_z) P_{EM}(k_z) \ dx \ dy \ dy \ dy,$$  \hspace{1cm} (E7)

Therefore, the final expression for the rms of the projected velocity field is

$$\langle V_{\text{rms}}^2 \rangle = \int P_{3D}(k_x, k_y, k_z) P_{EM}(k_z) P_{SH}(k_x, k_y) \ dx \ dy \ dy \ dy.$$  \hspace{1cm} (E8)

Moreover, the ratio of $V_{\text{rms}}^2$ and velocity dispersion along the line of sight is

$$\frac{\langle V_{\text{rms}}^2 \rangle}{\langle \sigma^2 \rangle} = \frac{\int P_{3D}(k_x, k_y, k_z) P_{EM}(k_z) P_{SH}(k_x, k_y) \ dx \ dy \ dy \ dy}{\int P_{3D}(k_x, k_y, k_z) P_{EM}(k_z) \ dx \ dy \ dy \ dy \ dy \ dy}.$$  \hspace{1cm} (E9)

This paper has been typeset from a TeX/BiX file prepared by the author.
