ABSTRACT

In this paper, we investigate the possibility of detecting lensing signals in high-resolution and high-sensitivity cosmic microwave background (CMB) experiments. At scales below 1 arcmin, the CMB background is dominated by the Sunyaev–Zel’dovich effect in clusters and by Ostriker–Vishniac effect distortions elsewhere. This uniform signal can be used as a background for lensing studies potentially allowing the detection of high-redshift clusters with none or little Sunyaev–Zel’dovich effect signal. We focus on the Ostriker–Vishniac effect and study the possibility of the detection of the lensing signatures by high-redshift clusters. We pay special attention to contaminants, such as instrumental noise and point sources. After designing an optimal filter for this particular lensing signal, we explore the signal-to-noise ratio for different scenarios varying the resolution of the experiment, its sensitivity and the level of contamination due to point sources. Our results show that the next generation of experiments should be able to introduce new and exciting science through the study of the Ostriker–Vishniac effect and its lensing effect.

Key words: methods: data analysis – galaxies: clusters: general – dark matter.

1 INTRODUCTION

Future high-resolution cosmic microwave background (CMB) or microwave experiments will focus on secondary anisotropies, such as the Sunyaev–Zel’dovich (SZ) effect (Sunyaev & Zel’dovich 1972), the Ostriker–Vishniac (OV) effect (Ostriker & Vishniac 1986) or the lensing effect. Both the SZ effect and the OV effect occur when free electrons interact with CMB photons. During this interaction, photons gain energy from the free electrons (this mechanism is known as inverse Compton scattering). This gain of energy creates a distortion in the energy spectrum of the CMB which is proportional to the temperature of the ionized plasma and its density (thermal SZ effect). Also, if the plasma cloud is moving with a bulk velocity $v$, this velocity creates an additional Doppler shift in the energy of the CMB photons (kinetic SZ). Historically, the thermal and kinetic SZ effects have been studied in galaxy clusters (non-linear regime). The OV effect is similar to the kinetic SZ effect but focusing on the first free electrons after reionization at high redshift (linear regime). The Universe is believed to be fully ionized at redshifts $z < 10$ (e.g. Loeb & Barkana 2001; Kohler, Gnedin & Hamilton 2007). At this high redshift, the temperature of the ionized medium is too low ($T \sim 10^4$ K) so the equivalent of the thermal OV can be neglected. High-resolution, high-sensitivity experiments should be able to see all three effects. In galaxy clusters, the thermal SZ effect is the dominant one followed by the kinetic SZ. The thermal SZ effect can be easily identified due to its frequency dependence. It should be, in principle, relatively easy to subtract this signal from the maps (see e.g. Herranz et al. 2002). The kinetic SZ can be partially removed using the spatial distribution of the thermal SZ and the fact that both effects are proportional to the optical depth of the cluster. However, internal dynamics in the cluster will leave residuals after the subtraction (Nagai & Kravtsov 2003; Mathis et al. 2005). On the other hand, the OV effect spreads over the entire field of view while the SZ effect is concentrated only in galaxy clusters. If one observes a small portion of the sky (a few arcmin$^2$), it is very likely that none or very few clusters will be present in the image and the OV effect may be the dominant anisotropy even before subtraction of the SZ effect. Having a high-redshift uniform background like the OV effect is particularly interesting for lensing studies. If a massive object (e.g. a cluster) is in the field of view, it will distort the OV effect creating an elongation on the anisotropies in a direction perpendicular to the direction of the projected gravitational force (in the strong lensing regime this elongation can be parallel to this direction, i.e. radial arcs). Lensing effect of the OV background opens a new door to study the distribution of high-redshift large-scale structures. In particular, it may be a powerful tool to study the evolution of galaxy clusters detecting proto-clusters at high redshift or dark clusters (i.e. no SZ or optical/radio emission) through their lensing effects. Future experiments should look for this signal as it offers a unique way to study the high-redshift universe. In the mm band, there are several experiments currently under development, ALMA (Atacama Large Millimeter Array; Wootten 2002), ACT (Atacama Cosmology Telescope; Kosowsky 2003), SPT (South Pole Telescope; Ruhl...
et al. 2004). Although it is very much possible that these experiments do not reach the required sensitivity, they will be important to address some of the issues discussed below, such as contamination by point sources. Also, high-sensitivity, high-resolution radio experiments will complement microwave observations by looking at the ‘holes’ in the 21-cm line maps (Wang et al. 2006), LOFAR (Low Frequency Array; Röttgering et al. 2003), SKA (Square Kilometre Array; Carilli et al. 2004). A technique similar to the one presented in this paper could be applied but using the 21-cm line as a background at even higher redshifts (Koopmans, Browne & Jackson 2004; Zahn & Zaldarriaga 2006). At frequencies below 10 GHz, one can observe free–free emission coming from the same ionized areas (at these frequencies, redshifted free–free could dominate over the CMB anisotropies; Oh 1999; Cooray & Furlanetto 2004). This signal is proportional to the square of the electron density and can create a pattern of structures with significant power at small scales which can also be used as a continuous background for lensing studies. While effects like the SZ effect have attracted much of the attention, little has been done regarding the OV effect (Jaffe & Kamionkowski 1998; Scannapieco 2000; McQuinn et al. 2005; Iliev et al. 2007) in part due to the difficulties found when simulating the OV effect. One of the main sources of uncertainty comes from the poor constraints on the reionization history [usually parametrized by the fraction of ionized material as a function of redshift Xe(z)]. Two kinds of constraints have been imposed so far. On one hand, studies of the Lyα forest have found that the Universe is completely reionized from redshift z = 0 to z ≈ 6. Observations of the Gunn–Peterson trough show that the end of the reionization era is at z ≈ 6 (Fan et al. 2002; Kashikawa et al. 2006). On the other hand, Wilkinson Microwave Anisotropy Probe (WMAP) polarization measurements of the CMB imply that reionization started at z = 10.9 ± 2.7 (Page et al. 2007). This constrain on the beginning of reionization was derived assuming that reionization was instantaneous. If reionization was a gradual process, then the starting point could be as high as z = 20. The higher the starting point of reionization, the denser the Universe was at that point and the strongest the OV distortions. Moreover, it is still uncertain how the different scenarios of patchy reionization affect the final distribution of OV anisotropies. The resulting uncertainty in the level of OV anisotropies (angular power spectrum) is about one order of magnitude (e.g. Santos et al. 2003).

Regarding lensing observations, most of them have focused on optical observations. Studies of strong lensing in galaxy clusters are particularly interesting since it is possible to have multiple arc systems coming from sources at different redshifts (Broadhurst, Taylor & Peacock 1995; Shapiro & Iliev 2000; Gladders, Yee & Ellingson 2002; Kneib et al. 2004; Broadhurst et al. 2005a,b). Through strong lensing, it is possible to estimate the projected mass of a cluster from 10 or a few tens of kpc to about 100 kpc. Weak lensing studies of galaxy clusters on the other hand allow to extend this range to the Mpc scale. Some work has been done to study the lensing distortions on CMB data by galaxy clusters. Most of these works focus on distortions of the primary CMB anisotropies or on angular scales larger than 1 arcmin (Seljak & Zaldarriaga 2000; Hirata & Seljak 2003; Lewis & King 2006; Hu, De Deo & Vale 2007). Previous works have tried to estimate the lensing effect on smaller scales over secondary anisotropies such as the OV effect (Zaldarriaga & Seljak 1999). These works propose methods to reconstruct the masses of galaxy clusters from their lensing signature. Due to its similarity, the reader may find the works by Hu (2001) and Maturi et al. (2005a,b) interesting. In those papers, the authors make use of filters for highlighting the lensing signals. In particular, Maturi et al. (2005a,b) define a filter which is formally similar to the one used in this paper although they apply it to lensed galaxies.

This paper will focus on the possibility of measuring the lensing effect due to high-redshift clusters through observations of the OV effect and its lensing distortions. We propose a new filter in Sections 2 and 3, test it with simulated data in Section 4 and show the significance of the results for various sensitivities, resolutions and point source confusion levels in Section 5. The same results could also be applied to potential observations of the reionization epoch by making high-resolution maps of the 21-cm line or free–free emission at those high redshifts. We will present a fast and efficient algorithm for highlighting lensing signals in noisy data which could be used for estimating the mass of high-redshift clusters.

2 Lensing Effect

The gravitational lensing effect can be quantified by the deflection angle, α, created by the distorting mass (or lens) over the photons. A source originally located on a position β in the sky will appear on a different position θ at a distance α from the original position

$$\beta = \theta - \alpha(\theta).$$

(1)

The deflection angle α(θ) at a given position is found by integrating the (perpendicular) change in the 3D gravitational potential, Φ, along the line of sight:

$$\alpha(\theta) = \frac{2}{c^2 D_D S_D} \int \nabla_\perp \Phi(\theta) d z.$$ 

(2)

Usually, the projected potential, ψ, is used instead of Φ

$$\psi(\theta) = \frac{2}{c^2 D_D S_D} \int \Phi(\theta) d z.$$ 

(3)

As a function of ψ, the deflection angle is just

$$\alpha(\theta) = \nabla \psi(\theta).$$ 

(4)

In the above equations, D_D, D_D and D_D are the angular diameter distances from the lens to the source (e.g. galaxy), from the observer to the lens and from the observer to the source. From the deflection angle, one can easily derive the magnification produced by the lens at a given position:

$$\mu^{-1}(\theta) = 1 - \frac{\partial \alpha_x}{\partial x} - \frac{\partial \alpha_y}{\partial y} + \frac{\partial \alpha_x}{\partial x} \frac{\partial \alpha_y}{\partial y} - \frac{\partial \alpha_y}{\partial x} \frac{\partial \alpha_x}{\partial y}.$$ 

(5)

Given the gravitational potential ψ, the shear is defined in terms of the second partial derivatives of the potential ψ (the Hessian of ψ): 

$$\psi_{ij} = \frac{\partial^2 \psi}{\partial x_i \partial x_j}.$$ 

(6)

$$\gamma_{11}(\theta) = \frac{1}{2} \left( \psi_{11} - \psi_{22} \right) = \gamma(\theta) \cos[2\varphi],$$ 

(7)

$$\gamma_{12}(\theta) = \psi_{12} = \psi_{21} = \gamma(\theta) \sin[2\varphi],$$ 

(8)

where γ(θ) is the amplitude of the shear and ϕ its orientation. The shear can also be expressed in terms of the deflection angle, α, yielding

$$\gamma_1 = \frac{1}{2} \left( \frac{\partial \alpha_x}{\partial x} - \frac{\partial \alpha_y}{\partial y} \right),$$ 

(9)

$$\gamma_2 = \frac{\partial \alpha_x}{\partial y} = \frac{\partial \alpha_y}{\partial x}.$$ 

(10)
2.1 Quantifying shear distortions in CMB maps

Weak lensing analysis historically has been applied to optical images where a large number of background sources (galaxies) are observed and their ellipticities measured. By averaging the ellipticities of many galaxies (∼100) over a given area (∼1 arcmin²), an estimate of the reduced shear, $g$, is obtained in that area. Repeating the same process over different contiguous areas, it is possible to give an estimate of the gravitational potential responsible for the measured average ellipticities. CMB maps are different because one lacks individual images (galaxies) and therefore it is not possible to define constrained images with well-defined borders for which an ellipticity (or orientation) can be derived. Instead, one deals with continuous fields (the OV effect or field $f$) having a typical anisotropy scale of 10–60 arcsec. For the discussion in this section, we will assume the field $f$ consists only of pure OV effect signal (with lensing distortions). In a real experiment, one will also have systematic noise and small-scale contaminants such as point sources. We will discuss these later. The anisotropies of the OV effect have intrinsic ellipticities which introduce random correlated shears on these scales of 10–60 arcsec. One expects the ellipticities of contiguous anisotropies (by contiguous we mean separated by more than ∼1 arcmin) not to be correlated so the mean orientation of a sufficiently large area should average to 0 (as it happens with the standard weak lensing of background galaxies). Given the scale of the OV effect, this means we should average areas of many arcmmin in order to reduce the intrinsic shear scatter of the OV effect. This poses a huge problem for lensing analysis since the typical scale of lensing signals is a few arcmin for distant moderate-mass clusters. Averaging the shear over many arcmin would wash out any lensing signal from these clusters. This is a problem which needs to be overcome. One option is to reduce the natural scale of the OV effect (or field $f$). This can be done by working with the curvature map, $C_f$, of the field $f$ instead. The curvature will reduce the large-scale component of the OV effect and will enhance small-scale fluctuations. Lensing signals will be minimally affected by this since the lensing stretches the anisotropies, therefore adding small-scale features which will be enhanced when we compute the curvature of the map. The curvature of $f$ can be defined as

$$C_f = \frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2}. \quad (15)$$

We can anticipate here that when dealing with noise data, the curvature would be dominated by the pixel noise. This problem can be significantly reduced by filtering out the noise (e.g. with a Gaussian filter) before calculating the curvature. We will discuss this point in more detail later.

The orientations (or shear) of the curvature field, $C_f$, can be constructed from the first derivatives of the curvature field. Based on these derivatives, it is possible to construct quantities similar to the Stokes parameters $Q$ and $U$.

$$Q = \frac{1}{2} \left[ \left( \frac{\partial C_f}{\partial x} \right)^2 - \left( \frac{\partial C_f}{\partial y} \right)^2 \right] = \frac{1}{2} (C_x^2 - C_y^2) \quad (16)$$

$$U = \frac{\partial C_f}{\partial x} \frac{\partial C_f}{\partial y} = C_x C_y' \quad (17)$$

An associated intensity $I$ can be defined as

$$I = \sqrt{Q^2 + U^2}. \quad (18)$$

For the sake of simplicity, from now on we will drop the suffix $c$ from $Q, U$ and $I$. We should note the correspondence between the...
definition of the quantities \((Q, U)\) and \((\gamma_1, \gamma_2)\). Like in the case of \(\gamma_1, Q\) is positive when the shear is aligned vertically while \(Q\) is negative when the shear is aligned horizontally. In the case of \(U\), the situation is similar but with a 45° rotation (like in the case of \(\gamma_2\)). The \(U\) parameter is maximum when the features are aligned over the 45° direction and minimum when they are aligned over the \(-45°\) direction.

For speed purposes, it is convenient to compute the curvature map \(C_f\) in Fourier space.

\[
C_f = -k^2 f, \tag{19}
\]

where the tilde denotes Fourier transforms, \(k = (k_x, k_y)\) is the Fourier \(k\) mode (or wave vector) and \(f\) is the original data.

Also, the first derivatives of the curvature map can be computed in Fourier space.

\[
C_{i} = i k_i C_f \tag{20}
\]

\[
\tilde{C}_{i} = i k_i \tilde{C}_f \tag{21}
\]

The Stokes parameter fields \(Q\) and \(U\) are obtained after Fourier transforming back to real space the complex maps \(C_i\) and \(\tilde{C}_i\) and substituting them in equations (16) and (17). Computing the derivatives this way has the advantage of being faster but it has the inconvenience of being affected by border effects (due to periodical boundary conditions in the Fourier transform). We can remove border effects by neglecting the areas near the image borders.

### 3 Optimal Filters for Lensing in CMB Data

The chances of detecting a weak signal embedded in a noisy background (in this case, the shear distortion created by a cluster in the CMB) can be greatly enhanced by using specifically tailored linear filters. The linear filters that maximize the signal-to-noise ratio \((S/N)\) of a given signal are known as linear matched filters (often referred to as optimal filters). A matched filter is obtained by correlating a known signal, or template, with the given data in order to detect the presence of the template in the data. In the presence of pure white noise, the shape of the filter is the same as the shape of the signal to be detected. However, when the noise has spatial correlations the noise covariance matrix (or, equivalently, its power spectrum) must be taken into account. The general form of the matched filter is proportional, in Fourier space, to the template of the signal over the power spectrum of the background. Matched filters have been widely used in engineering and data analysis for decades (Turin et al. 1960) and in many areas of astronomy, including detection of galaxy clusters in X-ray surveys (Vikhlinin et al. 1995; Stewart 2006), in 3D redshift surveys (Kepner et al. 1999), detection of extragalactic point sources in CMB maps (López-Caniego 2006) and detection of thermal SZ effect (Herranz et al. 2005; Melin, Bartlett & Delabrouille 2006). Besides, matched filters have been used for the detection of galaxy clusters through weak lensing (Maturi et al. 2005a, b). Bernstein & Jarvis (2002) presented optimal techniques to measure the weak gravitational shear from images of galaxies. In these works, matched or optimal filters for the shear were constructed. In this work, we will focus instead on designing matched filters for the Stokes parameters \(Q\) and \(U\) of the curvature field. After deconstructing the curvature map into its \(Q\) and \(U\) components (using the Fourier technique described above), we can apply an appropriate filter to highlight the expected lensing signal from a galaxy cluster. Optimal filters are generally defined (in Fourier space) as the signal (theoretical) we want to detect divided by the power spectrum of the background. The theoretical lensing signal can be computed numerically for a given profile calculating the deflection angles \(\alpha_x\) and \(\alpha_y\) and then the reduced shear \(g = (g_1, g_2)\).

Our basic assumption is that \(Q\) and \(U\) will show a pattern similar to the reduced shear if there is lensing signal in the data. The power spectrum of the background can be obtained directly from the data (in our case the power spectrum of the \(Q\) and \(U\) maps). The negative is that we need to assume a cluster profile in order to compute \(g\). This problem can be partially solved if we adopt a modified version of the definition of \(g\). We will assume the reduced shear can be well described by

\[
\hat{g}_1 = \gamma_1(1 + \kappa) \tag{22}
\]

\[
\hat{g}_2 = \gamma_2(1 + \kappa) \tag{23}
\]

We use the hat notation to distinguish between the formal definition of \(g_1\) and \(g_2\) (see equation 13). In the weak lensing limit where \(\kappa \ll 1\), equations (22) and (23) are similar to equation (13) (to the first order in \(\kappa\)). The above equations will fail in describing the correct shear where \(\kappa \approx 1\) or \(\kappa > 1\). This range corresponds to the strong lensing case. Our new definition for \(g_1\) and \(g_2\) will have no negative consequences if the strong lensing part of the data is omitted. This is exactly what we are going to do. By omitting the strong lensing part of the data, we avoid two important problems. On one hand, the Einstein ring shown in Fig. 2 disappears since with the new definition there is no change in sign when \(\kappa \approx 1\). This will make our results less sensitive (and therefore more robust) to any assumption about the specific profile of the cluster. On the other hand, by excluding the central region of the cluster we avoid some of the most serious contaminants, in particular the kinetic SZ effect due to internal bulk motions of the gas in the cluster and also mm or sub-mm extragalactic sources. The kinetic SZ cannot be removed with multifrequency observations (like the thermal SZ) since it does not depend on the frequency. Point sources within the galaxy cluster will be unresolved at the resolutions we are considering here [full width at half-maximum (FWHM) \(>5\) arcsec] and they can be very close to each other making the use of matched filters even harder due to their blending. One way to avoid the central region of the cluster is by means of a damping function, \(G(\sigma)\).

This leads us to the final form of the theoretical signal that we will assume for constructing the optimal filter

\[
\hat{g}_1 = \left[1 - G(\sigma)\right]^{2} \gamma_1(1 + \kappa) \tag{24}
\]

\[
\hat{g}_2 = \left[1 - G(\sigma)\right]^{2} \gamma_2(1 + \kappa), \tag{25}
\]

where \(G(\sigma)\) is a Gaussian function with dispersion \(\sigma\). The above definition introduces a scale \(\sigma\). The role of this scale is somewhat similar to the Einstein radius but with the difference that we only require that \(\sigma\) is of the order of the Einstein radius (a factor of 2 difference does not make a big difference as we will see below). Although we are not going to discuss about alternative choices for \(\hat{g}_1\) and \(\hat{g}_2\), we want to note that simplified versions of the reduced shear also gave good results when applied to our simulated data. In particular, due to its simplicity we can emphasize the following one:

\[
\tilde{g}_1 = \left[1 - G(\sigma)\right]^{2} \frac{x^2 - y^2}{x^2 + y^2} \tag{26}
\]

\[
\tilde{g}_2 = \left[1 - G(\sigma)\right]^{2} \frac{2xy}{x^2 + y^2}, \tag{27}
\]

where \(x\) and \(y\) are the distance to the centre of the cluster. This form reminds one of the kernel proposed by Squires & Kaiser (1996).
although the use of that kernel and our filter is different in each case.

In Fig. 3, we show the filter for $\sigma = 0.3$ arcmin (field of view of 12 arcmin). If the contaminants can be accounted for and removed, then the strong lensing signal could be measured as well. In this case, filters like $g_1$ and $g_2$ (see Fig. 2) may be more appropriate.

Once the expected signal has been defined, the optimal filters (one for $Q$ and one for $U$) are constructed in a standard way.

\[
\tilde{F}_Q = \frac{\tilde{g}_1(k)\tilde{b}(k)}{P_Q(k)},
\]

\[
\tilde{F}_U = \frac{\tilde{g}_2(k)\tilde{b}(k)}{P_U(k)},
\]

where, as above, tilde denotes Fourier transform. The term $\tilde{b}(k)$ is the Fourier transform of the kernel used to filter out the noise. We will discuss this factor in more detail later but we prefer to include it here for completion. We use a Gaussian kernel for $b$ with a scale larger than the resolution of the experiment. $P_Q(k)$ and $P_U(k)$ are the power spectrum of the $Q$ and $U$ maps, respectively (original data $\rightarrow$ filter noise $\rightarrow$ curvature $\rightarrow$ 1st derivatives $\rightarrow$ $Q$ and $U$) maps. As an estimate of the power spectrum of the background of $Q$ and $U$, we use the power spectrum of the computed $Q$ and $U$ maps. Note that these two maps also include the lensing signal, while formally we should exclude it. However, the contribution from lensing to the power spectrum of $Q$ and $U$ is negligible for the kind of data we are considering here (field of view, redshift of the lens and noise level). The two filters are convolved with the data and produce two filtered versions of the original data. We can just add linearly the two filtered maps together and look at the positive peaks in the combination map. Cluster candidates will always appear as positive fluctuations in the combined filtered map since negative $Q$s and $U$s due to lensing are multiplied by the corresponding negative and positive parts of the filters.

A very similar philosophy has been followed in the past to define optimal filters for weak lensing optical surveys (Maturi et al. 2005b). Although there are some differences, our filter and theirs are closely related. Some differences are the use of the damping function in our filter to reduce cluster contamination or the use of the total (background) power instead of the noise power spectrum in their definition of the filter. Also, in their work the authors apply their filter to simulated optical data (with background galaxies acting as the source plane for lensing).

4 SIMULATIONS

Testing the algorithm with simulations is essential, not only to prove its feasibility but also to identify its failures and weaknesses. We first simulate the OV effect when CMB photons cross the first newly reionized regions at high redshift. After the universe recombined at redshift $z \approx 1100$, it underwent a period know as the dark ages where the small density perturbations (of the order of $10^{-5}$ at redshift $z = 1000$) started to grow and form larger structures. During this period, the Universe was neutral and transparent to CMB photons. At some point around redshift $z \approx 20$, it is believed that the first stars and/or quasars reionized the medium around them (UV radiation). As the time passed, this newly reionized zones started to grow and merge forming larger and larger ionized areas. Free electrons in ionized regions would re-scatter a fraction ($\approx 10$ per cent) of the CMB photons (inverse Compton scattering). Due to the low energy of CMB photons, the scattering is elastic and isotropic (the scattered photon can leave the interaction in any direction). However, the CMB photon suffers a Doppler shift in its spectrum due to the electron’s motion. The distortion in the spectrum of the CMB photons is then proportional to the bulk velocity of the free electrons and their optical depth, $\tau$.

\[
\Delta T = -\frac{v}{c} \tau, \tag{30}
\]

with $v_r$ the radial component of the electron bulk velocity (or projection along the line of sight). As mentioned in the Introduction, the OV effect is similar to the kinetic SZ. However, the latter is always used to refer to hot ionized plasma in galaxy clusters while the OV effect focuses on ionized regions in much larger scales. In the Introduction, we also mentioned that the equivalent of the thermal OV effect can be considered negligible since the temperature of the intergalactic medium (IGM) is much smaller than in galaxy clusters ($T_{\text{IGM}} \approx 10^4$ K; Haehnelt & Steinmetz 1998; Hui & Haiman 2003).

Although the Universe is also ionized at low redshift, this distortion is expected to be dominated by the high-redshift Universe because it is denser by a factor of $(1+z)^3$. The interaction between the free electrons and the CMB photons will be then more likely at high redshifts. To simulate the OV effect, we use the public code GADGET-2 (Springel 2005). We make six different (dark matter only) simulations of 50 Mpc (comoving) cubes each and with more than two million particles per cube. For speed purposes, the gas was added afterwards assuming no bias (or a bias $b = 1$). Although assuming a bias $b = 1$ is not fully accurate, the corrections to the gravitational potential from the gas do not play a major role at the scales we are interested in. The simulation is started at redshift $z \approx 40$ and is run until $z \approx 3$. When projected, the cubes always have a scale larger than 20 arcmin for any redshift. We adopted a stacking procedure to project the simulations along the line of sight. We stack 45 projections of $12 \times 12$ arcmin$^2$ each (50 Mpc deep). This gives us a range in redshift between $z_{\text{min}} = 4.6$ and $z_{\text{max}} = 20.7$ (assuming $\Omega_m = 0.27$ and $\Lambda = 0.73$). This range of redshifts guarantees that we do not miss the beginning or end of the reionization epoch ($5 < z < 20$). Since we have only six independent simulations and in order to avoid correlated repetitions of the same projected zone, we rotate the cubes and/or take different patches or quadrants (of 12 arcmin each). We do not impose continuity conditions in the overlapping zone of the boxes but we expect this to be a minor systematic effect given the dimensions of the cubes. We assumed a patchy reionization and with a reionization history starting at redshift $z \approx 20$ and leading to a fully ionized Universe at redshift $z \approx 10$ (see Fig. 4). This ionization history is compatible with the upper limit of the latest WMAP constraints (Page et al. 2007). We assumed that high-density
regions were ionized first (Sokasian et al. 2003). Taking a homogeneous reionization instead reduces the OV power at small scales by a factor of 2 or 3. The OV effect is computed by projecting along the line of sight the radial velocity times the electron number density (which depends on the reionization history). The final map shows features at small and large angular scales. The rms peaks at scales between 20 arcsec and 1 arcmin (see Fig. 5) with values of the rms of $\approx 6 \mu K$. When compared with the CMB power spectrum, the OV spectrum dominates at scales smaller than 2 arcmin (assuming the contribution from instrumental noise, point sources and galaxy clusters can be removed). These results lay on the high end but are still comparable to previous estimations of this effect (Jaffe & Kamionkowski 1998). Our simulations are simplistic in the sense that we do not take into consideration all the physical processes involved in the ionization of the IGM. Instead, we reduce all the physics to the ionized fraction. However, these simulations will suffice for the purpose of this paper. The final map of the OV effect is used as a background template for computing the lensing effect of clusters at redshift $z = 1$ and assuming a NFW profile for the mass distribution. In our simulated cluster, we do not include either the thermal or the kinetic SZ effect. If these two effects are present, they could be included in the design of the filter and could help to increase the detection rate. This point will be discussed further later in the paper. The results of this paper should be considered a conservative estimate since we will assume that the cluster has no significant SZ signal. Also, in the simulations we have not included primary CMB anisotropies. The results of this paper would not change if we include them. At the scales considered here, the CMB would be just a gradient over the field of view with no effect over the results. We use the public package WSLAP for the computation of the lensing effect (Diego et al. 2005a,b, 2007). The resulting map is convolved with a Gaussian kernel to simulate the experimental beam and then is pixelized. We take three pixels per resolution element (FWHM). White Gaussian noise is added afterwards to account for instrumental noise. We will consider different noise levels and resolutions (4.2, 8.5 and 17 arcsec FWHM). More details on the resolution and noise levels will be given later.

Before showing our results, it is instructive to consider an ideal experiment with very good angular resolution and no instrumental noise. Fig. 6 shows our simulated OV background distorted by a gravitational lens in the middle of the field of view. We choose a relatively close ($z = 0.5$) massive cluster ($M = 10^{15} h^{-1} M_\odot$) to better illustrate this example. The more characteristic feature is the Einstein ring following the critical curve (left-hand panel). Lensing increases the power on smaller scales by stretching the anisotropies in the outer region of the Einstein ring and creating very small scale distortions inside this region. The lensing distortions are more evident if we look at the curvature map.
Lensing of the OV effect

This potential will introduce a distortion in the background sources. A convenient way of measuring this distortion is by looking at the distorted image of a circularly symmetric source. In the weak lensing regime, this distorted image will be an ellipse. From the shear $\gamma$ and convergence $\kappa$, we can compute the ellipse’s major and minor axes ($a$ and $b$, respectively) and the eccentricity $e$ (or ellipticity).

$$a = (1 - \kappa - \gamma)^{-1} = \frac{y}{y - 1} \quad (35)$$

$$b = (1 - \kappa + \gamma)^{-1} = 1 \quad (36)$$

$$e = \sqrt{1 - \frac{b^2}{a^2}} = \sqrt{1 + \frac{2y}{y^2} \approx \frac{2}{\sqrt{y}} = \frac{2}{R} \quad (37)$$

where in equations (35) and (36) we have computed $a$ and $b$ at the position $x = 0$ and $y = R$ (see below). To show how $Q$ and $U$ have similar properties, we will focus on just one anisotropy from the field $C$ at a distance $R$ and with ellipticity $e$. For simplicity, we assume that this anisotropy can be described by a Gaussian elongated in the horizontal direction. This is a simple way of simulating the lensing distortions suffered by the CMB anisotropies or a galaxy which is located to the north (or south) of the lens. Other choices for the field $C$ (like an ellipse) or positions in the field can be used as well to illustrate this point.

$$C = \exp \left[ -\frac{x^2}{2\sigma_a^2} - \frac{(y - R)^2}{2\sigma_b^2} \right] \quad , \quad (38)$$

where $\sigma_a$ and $\sigma_b$ play the role of the semi-axes $a$ and $b$ of an ellipse with eccentricity (or ellipticity) $e$ ($e = \sqrt{1 - b^2/a^2}$). We have also assumed that the elliptical Gaussian is placed on $x = 0$ and $y = R$. The values of $\sigma_a$ and $\sigma_b$ are arbitrary but we will assume that $\sigma_a > \sigma_b$. This situation corresponds to a Gaussian elongated in the horizontal direction. The corresponding $Q$ and $U$ parameters for $C$ are from equations (16) and (17)

$$Q = \frac{1}{2\sigma_a^2} C^2 \left[ \frac{x^2}{2} \frac{(y - R)^2}{1 - e^2} \right] \quad (39)$$

$$U = C^2 \frac{x(y - R)^2}{\sigma_a^2(1 - e^2)} \quad , \quad (40)$$

where we have substituted $\sigma_b$ by $\sigma_a(1 - e)$. Equations (39) and (40) have similar angular dependency to equations (31) and (32). The strength of the signal has to be obtained through integration of $Q$ and $U$. After integration, it is easy to find that the integrated signal of $U$ is zero as expected for this configuration while the integrated signal of $Q$ is

$$\int Q \sim \frac{\sigma_a^2}{\sigma_a^2 - \sigma_b^2} = \frac{\sigma_b^2}{1 - e^2} \approx e^2 \approx \frac{1}{R} \quad , \quad (41)$$

where in the approximation we have used the weak lensing regime approach $e \ll 1$ and the result obtained in equation (37). This last result proves that the expected magnitude of $\int Q$ decays with distance also as the shear does.

If the lens is asymmetric, so it will be the distribution of $Q$ and $U$. The information about the asymmetry of the lens can also be included in the definition of the filters.

5 RESULTS

As discussed above, in order to reduce the intrinsic shear of the OV effect we work with the curvature map instead. However, before computing the curvature the noise has to be filtered out since otherwise pixel-to-pixel variations due to the instrumental noise would dominate the curvature. For this purpose, we apply a Gaussian filter with a dispersion $\sigma_g$ which depends on the level of noise. For white Gaussian noise, the rms of the filtered noise decreases as $1/\sigma_g$. Depending on the noise level, we can choose the appropriate $\sigma_g$. For the noise level of the filtered map does not dominate the curvature of OV effect. Once the curvature map is computed, it is used to derive the $Q$ and $U$ maps of the data. These two maps are then optimally filtered and added to render the final result. In Fig. 7, we show an example for a cluster at redshift $z = 1$ and mass $M = 4 \times 10^{14} h^{-1} M_\odot$. The noise level was $3 \mu K$ per pixel and the beam of the experiment had a FWHM $= 8.43$ arcsec. The combination of $Q$ and $U$ filters produces a clear detection with a significance of 5$\sigma$. The rms $\sigma$ is computed in the area outside the white circle in the right-hand panel. The borders have been ignored because of systematic effects due to computations in Fourier space. It is interesting to note how the filter does not highlight features that at first can look like lensing effects. For instance, there is a round structure, similar to the lensing signal, on the top left side of the image. This structure is not enhanced at the same level as the real lensing signal.

The results will depend on the characteristics of the experiment: in particular on its sensitivity and resolution, but it will also depend crucially on other contaminants like the SZ effect in galaxy clusters.
(thermal and kinetic) and more importantly on the mm and sub-mm sources. The thermal SZ effect can be removed if several frequencies are available since this effect follows a well-established frequency dependence. The kinetic SZ on the other hand is frequency independent but it is proportional to the thermal SZ (at least the component due to cluster bulk motion) so it can also be partially removed. However, the removal might not be perfect and some residuals may be left especially in the central part of the cluster where energetic phenomena can create wave fronts or fast internal motions of the gas difficult to extract (Mathis et al. 2005). However, as mentioned earlier, our strategy to deal with these contaminants is neglecting the central regions of galaxy clusters by using a damping function in the centre of the filter. Our most worrying source of contamination will be point sources, but before studying their effect we will focus on the other aspects affecting the results.

### 5.1 Effects of the scale $\sigma$

First, we study the effect of the damping function discussed above. The role of this scale can be identified as the mass of the cluster. Increasing the scale $\sigma$ changes the optimal filters in a way that makes bigger scales more relevant. It also has an effect on the peaks of the signal. A large $\sigma$ not only removes more contributions coming from the central part of a cluster but also removes contributions coming from small-scale fluctuations in the curvature map. Hence, if there are still significant small-scale contributions to the curvature coming from instance from instrumental noise or point sources, the damping function helps to remove these signals. It is important to note that the effect of the smoothing function (used to filter out the noise before computing the curvature) is similar to the damping function.

When a smoothing kernel is applied over the theoretical shear, $\tilde{g}_1$ and $\tilde{g}_2$, it softens the peak compensating the positive and negative contributions at the centre. One could then be tempted to remove the damping function from the definition of the optimal filter, but this would have a negative effect on high S/N experiments where the noise does not pose a serious threat. In this case, filtering out of the noise is not necessary but still a damping of the filter in its centre is recommended to remove contaminants and reduce contributions from isolated peaks in the curvature map. In order to evaluate the effect of $\sigma$, we consider experiments with low noise (otherwise the effects of noise filtering can dominate the effect of the damping function). We find that a change in $\sigma$ of almost an order of magnitude renders basically the same number of detections ($S/N > 5$). Values of $\sigma$ much smaller than the expected Einstein radius of a cluster produce results which are very sensitive to isolated peaks in the curvature map. On the other hand, values of $\sigma$ much higher than a typical Einstein radius produce maps which are too diluted. Values for $\sigma$ in the range 20–60 arcsec produce in general satisfactory results. The small end will be more suitable for distant lower mass clusters while the higher end is more appropriate for detecting nearer massive clusters.

### 5.2 Effects of instrumental noise

We assume that instrumental noise can be well described by a Gaussian distribution with dispersion $\sigma_N$. We also assume that the noise is uncorrelated (white noise). In order to compare sensitivities, the noise is normally expressed as $\mu K$ per arcmin$^2$. We will follow the same notation and give our noise levels in the same units although in some cases it will be useful to express the noise in $\mu K$ per pixel.

At the scales of the resolution elements of our simulated data (4.2, 8.5 and 17 arcsec), the signal we are simulating (the OV effect) has a rms of a few $\mu K$. The noise level should be of the same order or below the signal level itself (otherwise the experiment would be noise dominated and we would not see any signal at all). This means that the noise per pixel should not be more than a few $\mu K$. This noise level per pixel translated into $\mu K$ per arcmin$^2$ gives $\approx 0.1 \mu K$ per arcmin$^2$. This sensitivity is, for today’s standards, about only one order of magnitude better than current experiments. In order to make a statistical analysis, we make 100 simulations for each case varying the noise (but keeping $\sigma_N$) and position of the cluster in each one. After taking different noise levels and applying the formalism discussed above, we compute the $S/N$ (for the 100 cases) as the ratio between the filtered signal at the central position of the cluster and the rms computed in the area excluding the cluster. The result as a function of noise level can be seen in Fig. 8. We plot $S/N$ and its dispersion (from the 100 simulations) for two cluster masses at redshift $z = 1$. In this result, the simulated experiment had a resolution of FWHM = 8.5 arcsec. From the plot, we see that for noise levels under $0.1 \mu K$ per arcmin$^2$ it is possible to detect a significant fraction of clusters down to masses of $M = 2 \times 10^{14} h^{-1} M_{\odot}$.

At noise levels of 0.5 $\mu K$ per arcmin$^2$, approximately half the clusters with...
masses $M = 6 \times 10^{14} h^{-1} M_\odot$ can be detected at these resolutions (in the absence of other contaminants). This mass is expected to be the largest cluster mass at $z = 1$. On the other hand, most of the low-mass clusters ($M < 2 \times 10^{14} h^{-1} M_\odot$) will be undetected with this noise level and resolution. A similar result is shown in Fig. 9 but this time fixing the noise level and varying the mass. Two noise levels are shown in the plot. The clusters are again assumed to be at $z = 1$. Both plots show larger variations in the S/N with increasing mass (even for smaller noise levels). The error bars depend on three factors. First, the noise level, second the background OV and third the fact that we use an optimal filter which depends on the background. The smaller contributions to the variation in the S/N are the noise level and the change in background which enters the definition of the optimal filter. Most of the variation in the S/N comes from the OV background behind the cluster (this can be seen as a cosmic variance uncertainty). A background rich in features and big changes in intensity will produce sharper arcs which will be more easily identified in the curvature map. On the other hand, if the OV background behind the cluster is smooth and poor in features, the lensing effect will show wide gradients in temperature rather than well-defined arcs. This second case will be much more difficult to detect through the shear distortions. Bigger clusters have a larger lensing cross-section. Hence, they are sensitive to a wider range of scales and consequently their S/N can change more.

5.3 Effects of spatial resolution

Spatial resolution plays an important role on the detectability of this effect. As discussed in the last paragraph in the last section, the detectability of a cluster depends very much on the OV background behind the cluster. If the background is rich in structure, the cluster will be detected more easily while if the background has small variations in intensity it will be more difficult to measure shear distortions. The beam of an experiment has two negative effects in lensing. On one hand, it rounds the anisotropies (if the beam is symmetric) reducing the shear of the anisotropy. On the other hand, it softens the anisotropies, removing variations in intensity smaller than the beam resolution. The ideal experiment will have a beam size smaller than the range where the rms of the OV anisotropies is maximum (20–60 arcsec). In this case, we will consider three beam sizes: 4.2, 8.5 and 17 arcsec. Larger beams will dilute the OV anisotropies hence making harder the detection of lensing signals. Also, larger beams make the issue of point source confusion a more serious one. On the other hand, a small beam is technologically more challenging since a larger collecting area is required and the sensitivity has to be increased accordingly with the resolution. In Fig. 10, we show the effect of changing the spatial resolution of the experiment while keeping its sensitivity (note that the noise per pixel must be different in each case to maintain the sensitivity). Again, we show the results for two different masses. Our results show that, in the range of resolutions relevant for the OV effect, the beam resolution of the experiment does not seem to have a large impact on the final results (although larger beams would start to reduce the S/N drastically). The explanation for why the resolution does not seem to affect the result is because we are setting the noise level per arcmin$^2$ the same for the three cases (resolutions). The same noise level per arcmin$^2$ implies, however, a higher noise level per pixel in the higher resolution experiment. This means that filtering out the noise has to be done with a Gaussian which in absolute terms is equivalent in the three cases. We could say that at the end the effective resolution is determined more by the noise level than by the experimental beam. Since in Fig. 10 the three experiments have the same noise level, the result is basically the same in all three cases.
5.4 Effects of point sources

Finally, we explore the most serious source of systematic error; extragalactic sources. To assess their importance, we simulate a population of point sources assuming they are observed at 1.2 mm (250 GHz). Due to the lack of observations at these wavelengths, little is known about the number counts in this range. Sub-mm and mm observations are still in their earlier stages. One of today’s most precise measurements of the number counts of galaxies at 1.2 mm wavelengths comes from the MAMBO (Max Planck Millimeter Bolometer) experiment (Smail, Ivison & Blain 1997; Hughes et al. 1998; Barger, Cowie & Sanders 1999; Bertoldi et al. 2000; Eales et al. 2000). A deep survey with MAMBO (Greve et al. 2004) revealed that number counts at 1.2 mm were about one order of magnitude less than at 850 μm (SCUBA number counts). This drop in the number counts is partially due to the fact that mm sources are generally dimmer when wavelength increases. In particular, combining MAMBO and SCUBA sources one finds that the ratio of fluxes $S_{350\mu m}/S_{1200\mu m}$ is about a factor of 3 (Greve et al. 2004). At even longer wavelengths, one expects that number counts are even smaller. This suggests that observing at frequencies around 100 GHz might be optimal to reduce the negative effects of point sources. To simulate the point sources at 1.2 mm, we use the MAMBO number counts of Greve et al. (2004). In the same paper, the authors compare their number counts with models having different galaxy evolution. These models are compatible with both SCUBA and MAMBO number counts. Due to the lack of information below 1 mJy (at 250 GHz or equivalently 1.2 mm), we extrapolate the model to lower fluxes to account for the dimmer sources. We consider two different extrapolations that are compatible with the observed number counts. In Fig. 11, we show the integrated number counts of our two models. The flattening of the integrated number counts at low fluxes in Fig. 11 is predicted by simulations (Fardal et al. 2001). In our calculations, we assume that we can remove all sources above a given flux. Sources need to be subtracted before filtering out the noise and computing the curvature of the map. In this paper, we assume the sources can be removed perfectly. This is an optimistic assumption as subtraction algorithms always leave a small residual. It is beyond the scope of this paper to study the effects of these residuals here and we will focus only on the negative effects of the sources which cannot be removed. For the sake of simplicity, our sources are simulated assuming that they are not affected by lensing distortions. This approximation is valid if the angular resolution of the experiment is substantially larger than the typical size of galaxies. With the resolutions considered in this work (FWHM ≈ 8 arcsec) all our sources will be unresolved. We should note that by doing this approximation we are being conservative since sources might actually help to highlight lenses since they could introduce shears in the maps. However, we will not consider this case in this work. In order to check the effect of point sources, we will add a population of sources up to a given flux cut. All sources above this flux cut are assumed to be removed from the map. Fig. 12 summarizes our findings for three different cuts in flux. Our result predicts that sources are a major contaminant and that they need to be removed down to the μJy level (at 1.2 mm). This will be a serious issue which needs to be investigated further but is not in this paper. For instance, multifrequency observations might be required to reduce the level of contamination of mm sources.

6 DISCUSSION OF THE RESULTS

Our simulations show how an experiment with a resolution of FWHM ≈ 8 arcsec and sensitivity of $\sigma_N \approx 0.2 \mu K \ h^{-1} \ M_\odot$ could detect high-redshift galaxy clusters through their lensing signature on the OV anisotropies. Experiments like ALMA will be soon near this limit. Current experiments like the Atacama 25-m telescope (ACT) can reach sensitivities of ≈2 μK with beams of 1.7 arcmin or less at mm frequencies (Kosowsky 2003). The main limiting factor to detect distant clusters through OV lensing will be our ability to subtract point sources. Our simulations show how one needs to subtract sources down to a few μJy (at $\lambda = 1.2 \ mm$) in order to observe the OV anisotropies and their lensing distortions. In the flux range 1–3 μJy (or 2–6 μK per beam), one expects nearly one source per beam (FWHM ≈ 8 arcsec). Although the μJy level may seem unreachable, we have to note that sources above 3 μJy flux can be seen as $\approx 5 \sigma$ fluctuations with the sensitivities considered in this paper ($0.2 \mu K \ arcmin^{-2}$). Therefore, it should be straightforward to subtract them. Also, even for lower flux sources, the fact that their flux vary with frequency (while the OV effect does not) can be used to develop subtraction algorithms for multifrequency maps (Herranz et al. 2002). These algorithms can also use information about the shape of sources (which at these resolutions will be unresolved) to define a matched filter. Another limiting factor will be the sensitivity of the instrument. We estimate that sensitivities below
0.2 μK arcmin$^{-2}$ are necessary in order to reliably detect lensing signals. This level of sensitivity is about one order of magnitude better than current experiments. ALMA for instance expects sensitivities (in the continuum) of about 40 μJy with only 60 s integration in the frequency band 125–163 GHz (Wootten 2002). Longer integration times would increase the sensitivity, thus allowing to observe the OV anisotropies (6 ks would increase the sensitivity one order of magnitude to 4 μJy or equivalently 8 μK per beam of 8 arcsec). Regarding the spatial resolution of the experiment, we found that this is not as important as long as it is better than ≈10 arcsec. Smaller beams though, will allow a better subtraction of point sources. These kinds of resolutions can be obtained with large single dish telescopes (Gran Telescopio Milimétrico/Large Millimeter Telescope; Carrasco, Recillas & Schloerb 2004) or interferometers (ALMA). Achieving these sensitivities and resolutions will open a new window for cluster studies, allowing the detection (and mass estimation) of high-redshift clusters even before they can be observed by other means. This is particularly interesting since at high redshift the geometric factor in the lensing signal decreases more slowly than at lower redshifts. For example, increasing the redshift of the cluster from $z = 1$ to $4$ decreases the amplitude of the lensing signal only by a factor of 2.

Other possible sources of contamination not considered in this paper are signatures from large-scale structure (projected SZ, Ress–Sciama, correlated sources). If these structures are behind the lens, they would also suffer lensing distortions which would show up in the $Q$ and $U$ maps helping to detect the lens. If the structures are in front of the lens, they would have a negative effect by adding a signal which is not lensed to the lensed signal.

### 6.1 Alternative choices for the filter

It is interesting to note that there is still room for improvement. For instance, we have presented results for an optimal filter but other choices could render similar results. An interesting alternative is the operator defined by Kaiser & Squires (1993). In equation (2.1.12) of that paper, they derive the Fourier transform of the mass surface density as

$$\Sigma(k) = -\chi_1(k)\tilde{e}(k),$$

where $k$ is the wave vector in Fourier space, $\tilde{e}(k)$ is the Fourier transform of the ellipticity and $\chi(k)$ is the operator.

$$\chi_1(k) = \frac{k_1^2 - k_2^2}{k_1^2 + k_2^2}$$

$$\chi_2(k) = \frac{2k_1k_2}{k_1^2 + k_2^2}.$$  

Taking $Q$ and $U$ as our estimates of the ellipticities and applying equation (42) render results very similar to the ones presented in this work after the $Q$ and $U$ maps are averaged over scales of 20–30 arcsec. We should note that while our filter acts as a convolution over the $Q$ and $U$ maps, the Kaiser and Squires operator acts as a combination of second derivatives of the $Q$ and $U$ maps.

### 6.2 Possible biases and future developments

The analysis presented in this work is not intended for estimating the lensing potential. The purpose of the filter is to highlight lensing signatures over a noisy background. The filter, in principle, does not provide any estimate of the underlying potential (although it could be easily calibrated with simulations). One of the problems which need to be overcome in the future is the issue of possible systematic biases. One of the most evident ones is the fact that the typical scales of the OV effect are in the arcmin range. Over these scales, it is not possible to assume that the deflection angle is constant across the structure being lensed (as it is usually assumed in standard lensing analysis). This assumption could introduce biases in the final result if one attempts to reconstruct the lensing potential.

In our case, however, this is not a problem since we aim at just finding the lensing candidates in the microwave background without estimating their potential. Future work will be needed to improve these techniques and develop unbiased algorithms for estimating the lensing potential.

Earlier in the paper, we introduced the idea that the filter could be adapted to include possible SZ signals (thermal and kinetic). This possibility has not been explored in this paper where we focused only on the lensing signatures, however it has the potential to improve the cluster detection rate and should be explored. The filter can be modified by including the expected $Q$ and $U$ for a combination of thermal and kinetic SZ. The damping function should be substituted by this new function which now would be different for the $Q$ and $U$ filters. Both the thermal and kinetic SZ can be modeled to first order assuming a $\beta$-model. The expected $Q$ and $U$ of the combined SZ signal can be included in the definition of the filter. Second-order corrections (shocks, internal dynamics, departures from isothermality, etc.), especially in the case of the kinetic SZ, can make the structure near the central part more complex and difficult to model. We should emphasize that $Q$ and $U$ are insensitive to the sign of the anisotropies of the field $C$. This means that the sign of the kinetic SZ does not play any role other than changing the normalization of the combined thermal plus kinetic SZ. Another alternative is to combine the results obtained from a standard matched filter (e.g. Herranz et al. 2002, 2005) and the filter presented in this work. In this case, the damping function can be used to suppress the SZ signal in the centre of the cluster. However, the SZ signal could still affect the result by interacting with the lobes of the filter when this is not aligned with the cluster. This effect would be similar to the point sources.

### 7 Conclusions

The OV effect can create anisotropies of a few μK on scales of 10–30 arcsec. A galaxy cluster can distort the OV effect background creating a distinctive lensing signature. This distortion produces a shear of the OV anisotropies which can be highlighted with an appropriate filter. We have seen how an optimal filter can be built for the Stokes parameters of the curvature map of the image. We test the potentiality of the filter to highlight lensing signals with simulated data. The simulated data include different levels of instrumental noise, angular resolution and point source contamination. We study how the instrument characteristics and point source contamination affect the result, finding that point sources might be the most serious problem and that it will be necessary to subtract them down to the μJy level at mm wavelengths. The effort to go down to this level should be rewarding. These types of studies would open a new and exciting window to explore cluster formation, since it would allow to detect and estimate the mass of high-redshift clusters through their shear distortions. A more careful analysis of the lensed images could predict the mass of the cluster with better accuracy. For instance, the Einstein radius could be easily identified in many cases since a continuous background guarantees that there will always be photons originating at the caustics.
