Keywords
Gastric cancer · Peritoneal carcinomatosis · Hyperthermic intraperitoneal chemotherapy · Cytoreductive surgery · Complications

Abstract
Introduction: Patients with advanced gastric cancer (AGC) frequently show peritoneal carcinomatosis (PC). PC reduces life expectancy and quality of life. Cytoreductive surgery (CRS) with hyperthermic intraperitoneal chemotherapy (HIPEC) has been shown to improve overall survival. Nevertheless, it has been reported that CRS and HIPEC are accompanied by an increase in postoperative complications. The purpose of this study was to investigate the complications associated with CRS and HIPEC and overall and disease-free survival. Methods: Patients with AGC and PC, who received complete CRS and HIPEC, were included in the HIPEC group (n = 15). Patients with AGC but without PC, who received resection of the primary tumor alone, constituted the control group (n = 43). Results: Patients enrolled in the HIPEC group presented with a median PCI of 7. In comparison with the control group, no differences were found in patient characteristics, risk factors, pathological findings, and operative procedures. Twenty-five percentage of the patients in both groups suffered from serious postoperative complications (CDC ≥3a). Surgical and medical complications, rate of reoperation, and mortality did not differ. Also, the recurrence pattern, median survival, and 1- and 2-year survival rates showed no differences. Conclusion: CRS and HIPEC do not lead to an increased postoperative morbidity and mortality in AGC with PC. Albeit the poorer prognosis of patients with PC, survival of both groups was comparable.

Introduction
Gastric cancer is a worldwide healthcare burden, being the sixth most commonly diagnosed cancer and the third leading cause of cancer-related death in 2020 [1]. The combination of late onset of symptoms and the absence of a screening program in most countries often results in an advanced disease stage at the time of diagnosis. Therefore, 39% of patients are diagnosed at a locally advanced tumor stage, while 40% already show distant metastatic spread that goes hand-in-hand with a dramatically reduced life expectancy [2]. The peritoneum is a frequent metastatic site, especially for the diffuse subtype of gastric cancer, occurring in approximately 55% of patients [3]. The median overall survival (OS) of patients with untreated peritoneal carcinomatosis (PC) amounts to 3 months [4]. Although palliative chemotherapy has been shown to prolong survival in patients with distant metastases (i.e., in the liver and/or lung) up to 11–13 months, the benefit for patients suffering from PC is unclear [5, 6].
In addition, the presence of PC has a higher influence on the quality of life of patients compared to other metastatic sites due to often occurring abdominal pain, severe ascites, and ileus [7].

Within the last decade, the combined therapeutic approach of cytoreductive surgery (CRS) with hyperthermic intraperitoneal chemotherapy (HIPEC) has been established. Since the technique was first described in the 1990s, it is nowadays frequently performed in specialized surgical centers [8]. CRS and HIPEC has increased the OS of gastric cancer patients with PC up to 10–16 months [9–11]. Some studies suggest that this benefit is at the expense of increased postoperative complications, adding to the already high rate of severe complications after gastrectomy alone of up to 36.7% of all cases [12]. An increase in the frequency of the grave complication anastomotic leakage as well as wound infections after HIPEC has been described [13–15]. Studies investigating postoperative complications after HIPEC are scarce, but urgently needed for evidence-based decision-making. As important as documenting is the scoring of complications in a systematic manner. To this end, the Clavien-Dindo Classification (CDC), a well-established scoring system for postoperative complications, can be used [16]. To summarize all incurred complications, the Comprehensive Complication Index (CCI) has been established. The CCI is a single score that reflects the total sum of weighted single complications’ severity [17]. The purpose of this study was to investigate the complications associated with CRS and HIPEC and to compare overall and disease-free survival to gastrectomy alone.

Materials and Methods

Statement of Ethics

The study was approved by the Ethics Committee of the Technical University of Dresden (BO-EK-431092020). All procedures performed in this study involving human participants were in accordance with the 1964 Declaration of Helsinki and its later amendments.

Patient Selection

All patients, who underwent gastrectomy with CRS and HIPEC in the University Hospital of the Technical University Dresden between 2013 and 2019 that did not meet any exclusion criteria, were included in the study (HIPEC group, n = 15). Exclusion criteria were defined as a previous/concurrent second malignancy, previous extensive abdominal surgery, and substantial medical comorbidities like acute pancreatitis or coronary heart disease with instable angina pectoris. The control group included all consecutive patients that received a curative intent gastrectomy from the same time period due to locally advanced gastric cancer (pT3–4, pN1–3) but without PC and not meeting exclusion criteria (non-PC group, n = 43).

Performed Treatments Including Surgery and HIPEC

Neoadjuvant treatment was performed in case clinical staging indicated a primary tumor of T >2 and/or presence of lymph node metastases. Primary workup included a gastroscopy with histological confirmation and a CT scan of the thorax and abdomen. In case neoadjuvant chemotherapy was planned, a laparoscopy was also part of the primary workup. Primary tumor resection was performed according to histological subtype and location: diffuse type cancer was resected with a gastrectomy and intestinal type cancer was resected with minimum 8-cm distance to the tumor, resulting in subtotal resections in case parts of the proximal corpus and/or fundus could be preserved. The extent of surgery in both groups included a subtotal, total, or transhiatal extended gastrectomy via laparotomy with a lymphadenectomy depending on tumor location. If necessary, a multivisceral resection with splenectomy, (left) pancreatocystojejunostomy, and/or hemicolectomy was conducted. All patients were reconstructed with a Roux-Y gastro- or esophageo-jejunostomy.

The decision to perform CRS and HIPEC was based on a PCI ≤12 and the possibility to reach a (near) total cytoreduction (Completeness of Cytoreduction Score of 0–1). CRS and HIPEC was not indicated if other nonresectable distant metastases existed or if patients were unfit for surgical resection or had known contraindication to intraperitoneal chemotherapy. The Peritoneal Cancer Index (PCI) was calculated after laparotomy in patients with PC according to Sugarbaker [18]. In the HIPEC group, CRS was performed by additional peritonectomy of PC lesions with the goal of achieving a complete cytoreduction. In 10 patients, the oncological resection was directly followed by HIPEC. In the remaining 5 patients, HIPEC was applied depending on the extent of surgery in a 2-staged procedure 5–6 days following the primary resection. Routinely, 2 afferent and 3 efferent drainages were placed and connected to the HIPEC pumping system. In 14 patients, HIPEC was performed with i.p. oxaliplatin (350 mg/m²) heated to 41.5°C (±0.5°C) for 30 min and an i.v. injection of 5-FU (400 mg/m²) and calciumfolinate (20 mg/m²). In 1 case, the patient refused systemic chemotherapeutic treatment, and therefore doxorubicin (15 mg/m²) and cisplatin (50 mg/m²) were applied i.p. for 60 min with a temperature of 41.0°C.

Morbidity Grading

The analysis of postoperative complications was performed by 2 independent physicians by a systematic inspection of patient charts and medical files. In total, 17 frequent and severe postoperative complications after gastrectomy were evaluated: anastomotic leakage, duodenal stump insufficiency, pancreatic fistula, bleeding, intra-abdominal abscess, wound infection, wound dehiscence, (paralytic) ileus, pneumonia, respiratory insufficiency, prolonged ICU stay, arrhythmia, renal insufficiency, thromboembolic events, cardiac decompensation, bacteremia/sepsis, and multiple organ failure [19,20]. The extended CDC of the “Japan Clinical Oncology Group” was used to quantify postoperative morbidity [21]. All of the aforementioned complications that occurred within the first 90 postoperative days and were related to surgery were recorded. Next, the complications were weighted according to the CCI.

Follow-Up

Patients were followed up according to a standardized protocol at our University Cancer Center (UCC Dresden). This included a periodic clinical and imaging follow-up after surgery or completed adjuvant chemotherapy with CT scan and endoscopy every 6 months for 5 years. If necessary, a further diagnostic evaluation (e.g., endoscopic biopsy and re-laparotomy) was performed.

Statistical Analysis

To determine statistical differences between both groups, Fisher’s exact test was used. The evaluation was performed with Student’s t test for metric, normal distributed variables and with the

Mann-Whitney U test for nonparametric variables. OS and disease-free survival (DFS) were analyzed with the Cox-regression and log-rank test and were represented as Kaplan-Meier curves. Significance level was set to 0.05. The entire statistical analysis was performed in SPSS 25 (SPSS Statistics, v25.0.0.2; IBM Corporation, Armonk, NY, USA).

The manuscript is STROBE compliant. For STROBE checklist, please see online supplementary material (for all online suppl. material, see www.karger.com/doi/10.1159/000520330).

Results

Patient Characteristics, Pathological Findings, and Operative Procedures
In total, 58 patients with locally advanced gastric cancer that underwent subtotal, total, or transhiatal extended gastrectomy with lymphadenectomy were analyzed. Fifteen patients with PC received additional CRS and HIPEC. The control group consisted of a cohort of 43 patients with advanced gastric cancer without PC. Baseline characteristics such as age, sex, risk factors, and tumor localization were not statistically different in the 2 groups (Table 1). No difference in histological findings, that is, Lauren classification or differentiation grade, was found. As expected, the amount of signet ring cells as defined by the WHO (nucleus pressed to the cell edge, PAS-positive intracellular mucus) was significantly higher in the HIPEC group (60.0% vs. 25.6%, \( p = 0.019 \)). The pathological findings for T and N stage did not differ. Four patients in the non-PC group showed concomitant liver metastasis, which were resected in sano by atypical liver resection. A trend toward more neoadjuvant chemotherapy in the HIPEC group was detected (87.7% vs. 62.8%, \( p = 0.077 \)), while the frequency of administered adjuvant chemotherapy was similar (64.3% vs. 70.0%, \( p = 0.467 \)). Reasons for not administering neoadjuvant chemotherapy were old age with comorbidities or reduced condition (\( n = 9 \)), primary resection requested by the patient (\( n = 5 \)), no indication based on preoperative staging (\( n = 3 \)), and pyloric stenosis with inability of food intake (\( n = 1 \)). Reasons for not administering adjuvant therapy were old age with comorbidities or reduced condition (\( n = 7 \)), refusal of chemotherapy (\( n = 7 \)), 8 or more cycles of preoperative chemotherapy, and therefore no indication for additional postoperative treatment (\( n = 2 \)), and change to palliative situation due to tumor progress (\( n = 1 \)) (online suppl. Table 1). The surgical procedures including lymph node yield were distributed similarly between the 2 treatment groups with the exception of a higher proportion of patients with a positive resection margin (R1) in the HIPEC group (33.3% vs. 9.3%, \( p = 0.041 \)). In all patients of the HIPEC group, a Sugarbaker completeness of cytoreduction score (CCS) of 0—1 could be achieved. Median PCI was 7 (IQR 3—10) in the HIPEC group (Table 1).

Morbidity and Mortality
Complications were considered serious if they required a surgical, endoscopic, or radiological intervention or intensive care (CDC score ≥IIIa). Approximately one-quarter of the patients in both groups had one or more complications with a CDC score ≥IIIa (26.7% vs. 25.6%, \( p = 0.592 \)) (Table 2; online suppl. Table 2). Likewise, the mean CCI (weighted sum of all complications) did not differ between both groups (19.4 vs. 18.1, \( p = 0.268 \))

Table 2. Morbidity and mortality

|                      | HIPEC, \( n = 15 \) | Non-PC, \( n = 43 \) | \( p \) value |

Values are n (%) unless otherwise indicated. CDC, Clavien-Dindo Classification; CCI, Comprehensive Complication Index; SD, standard deviation. † Fisher’s exact test. * Mann-Whitney U.
Complications after CRS and HIPEC in Gastric Cancer

We also did not detect significant difference between the groups, when analyzing the most frequent and severe surgical or medical postoperative complications individually. Although there were twice as many wound infections in the HIPEC group, this difference turned out to be not significant (20.0% vs. 9.3%, \( p = 0.408 \)). The number of reoperations (13.1% vs. 14.0%, \( p = 0.662 \)) and 90-day postoperative readmission rate (7.1% vs. 9.3%, \( p = 0.614 \)) were similar in both groups. The addition of CRS and HIPEC did not increase the 30-day mortality (6.7% vs. 4.7%, \( p = 0.600 \)). Of note, in 2 patients, adverse events directly associated with HIPEC were observed: one allergic reaction that led to immediate termination of the HIPEC procedure and one pancytopenia, which resulted in septic multiple organ failure and death.

**Recurrence and Survival Analysis**

The total recurrence rate (85.7% vs. 65.0%, \( p = 0.130 \)) and the rate of peritoneal recurrences (57.1% vs. 37.5%, \( p = 0.167 \)) were each approximately 20% higher in the HIPEC group, but proved to not be statistically significantly different (Table 3). The median time between surgery and first recurrence was 8.5 months (4–17.5 months) in the HIPEC group and 7.5 months (4–13 months) in the non-PC group (HR 0.808, 95% CI: 0.382–1.709, \( p = 0.578 \)). Of note, the time between surgical resection and first peritoneal recurrence was similar in both groups (8.5 months vs. 8.0 months, HR 0.643, 95% CI: 0.241–1.715, \( p = 0.377 \)). The 1- and 2-year survival was 60.0% and 26.7% in the HIPEC group and 67.4% and 30.2% in the non-PC group (\( p = 0.850 \)). The median OS time after surgery was 12 months (9–26 months) in the HIPEC group and 15 months (9–32 months) in the non-PC group (HR 1.240, 95% CI: 0.616–2.495, \( p = 0.546 \)). The median OS time from date of diagnosis was 21 months (14–30 months) in the HIPEC group and 18 months (13–24 months) in the non-PC group (HR 1.054, 95% CI: 0.524–2.121, \( p = 0.882 \)). No difference in Kaplan-Meier curves for OS (\( p = 0.538 \)) and DFS for PC (\( p = 0.558 \)) after 2 years of follow-up was observed (Fig. 1).

Within the HIPEC group, 4 patients with PCI \( \leq 6 \) (\( n = 7 \)) and 4 patients with PCI >6 (\( n = 7 \)) developed a PC recurrence (57.1% vs. 57.1%, \( p = 0.704 \)). While the recurrence rates in both groups were similar, the median survival of patients with lower PCI was significantly different with 20 months (12–47 months) compared to 9 months (7–14 months, \( p = 0.015 \)) in patients with higher PCI. In line with this, Kaplan-Meier curves documented a clear trend toward a difference in OS depending on PCI (\( p = 0.051 \)) (Fig. 2).

**Discussion**

The “peritoneal-blood-barrier” between the submesothelial tissue and peritoneal surface limits nutrient and oxygen transport. This barrier function is thought to reduce the effectiveness of systemic chemotherapy [22, 23]. Based on this hypothesis, the concept of intraperitoneal chemotherapy was developed and nowadays performed in conjunction with hyperthermia (HIPEC). Nevertheless, the HIPEC procedure is still controversially discussed. One of the frequently voiced fears is the increased morbidity and mortality of CRS and HIPEC in addition to the already major surgery of the primary tumor. Mortality is reported to range between 5.2% and 11.7% after gastrectomy [12, 19] and 3% and 10% after CRS and HIPEC for gastric cancer [24]. In accordance with this, we found a mortality rate of 6.7% and 4.7% in the HIPEC and non-PC groups, respectively. The morbidity of total or subtotal gastrectomy for cancer varies from 17% to 43% [25], and major postoperative complications (CDC

| Table 3. Recurrence and survival |

Values are \( n \) (%). All continuous numbers are median values with the interquartile range (IQR) in brackets. PC, peritoneal carcinomatosis. † Fisher’s exact test. ‡ Log-rank test.
≥IIIa) are reported to occur in 9.8–18.9% of all cases [15, 26]. The mean CCI after gastrectomy ranges from 5.8 to 9.4 in the literature [27, 28]. Mielko et al. [29] reported higher morbidity rates after CRS and HIPEC with a mean CCI of 42.7 (SD 22.7). We observed one or more postoperative complications with CDC ≥ IIIa in approximately one-quarter of patients in both the HIPEC and the non-PC group, and the mean CCI was 19.4 and 18.1, respectively. Of note, we have included 17 distinct complications into our analysis, surpassing the usual 8–10 complications taken into account by previous publications. While the CCI for the HIPEC group was thus better than what has been published before, the frequency of complications with CDC ≥IIIa was above the frequency previously reported for total or subtotal gastrectomy. However, our non-PC cohort included only advanced gastric cancer (pT3–4, pN1–3), and one-third of patients underwent extended resections, which influences the frequency and severity of morbidity.

When focusing on individual postoperative morbidities, a large analysis of 37,440 German patients, which received subtotal or total gastrectomy, revealed morbidity rates for anastomotic leakage of 9.7%, pneumonia of 12.3%, and sepsis of 18.3% [12]. In our non-PC group, the rates of these complications are in part distinctly lower with 9.3%, 2.3%, and 7.0%, respectively. In the literature,
an increased risk after HIPEC for developing an intra-abdominal abscess, respiratory failure, or renal dysfunction is described [24, 30]. In our analyses, no significant differences in surgical and medical complications between the HIPEC and non-PC group were found. Thus, no increase in the frequency of CDC ≥IIIa and CCI nor in individual morbidities was seen in our comparison. This is of importance, as it has been argued that performing CRS and HIPEC delays additive chemotherapy because of postoperative complications and a general longer recovery time after surgery [24]. We could demonstrate for our patient cohorts no significant difference in the rate of administered adjuvant chemotherapy.

In patients with advanced gastric cancer and curative resection, the most common site of recurrence is the peritoneum with approximately 39% [31]. Consistent with this, we found a PC recurrence rate in our control cohort of 37.5%. The median time for developing a PC recurrence was 8.5 months in the HIPEC group and similarly 8 months in the non-PC group. The recurrence pattern after CRS and HIPEC is not well examined. Rosa et al. [32] showed a PC recurrence rate of 57% after CRS and HIPEC for primary PC and of 59% after surgery alone in advanced gastric cancer. In our HIPEC cohort, 57.1% patients developed a peritoneal recurrence. In other words, this implicates that in 42.9% of the patients, PC did not return until death or within the follow-up period. CRS and HIPEC thus results in a similar time interval to PC recurrence between patients with and without PC, while a large proportion does not experience a relapse. This is of importance, as the quality of life of patients declines in the presence of untreated PC due to often occurring abdominal pain, severe ascites, and ileus [33]. A systematic review could demonstrate that the quality of life measured by standardized questionnaires initially decreases after CRS and HIPEC, but recovers to preoperative levels by 6–12 months after surgery [34]. Moreover, it could be shown that patients suffering from symptomatic malignant ascites profit the most from CRS and HIPEC in terms of quality of life [35].

Several studies have indicated positive effects of CRS and HIPEC in gastric cancer patients [36, 37]. In a large multi-institutional study, Glehen et al. [38] could document in 159 patients with gastric cancer and PC treated with HIPEC and/or early postoperative intraperitoneal chemotherapy a median OS of 9.2 months and a 1-year survival of 43%. The cohort included patients with high PCI of >19. In a subgroup analysis of patients with CCS 0–1, the median survival was 15 months. Up to today, Yang and colleagues [9] performed the only larger randomized controlled trial comparing CRS and HIPEC to CRS alone for gastric cancer with PC. A significantly better median OS of 11.0 months in comparison with 6.5 months for the CRS and HIPEC group versus CRS alone was described. The 1- and 2-year survival rates were 41.2% and 14.7% for CRS and HIPEC and 24.9% and 5.9% for CRS alone [9]. In a meta-analysis, 289 patients undergoing CRS and HIPEC for gastric cancer and PC were evaluated revealing a median OS of 11.1 months [24]. With a median OS of 12 months and 1- and 2-year survival rates of 60.0% and 26.7%, we observed similar results in the present study within the HIPEC group. Of note, we could document in our analysis that the life expectancy of patients with primary PC after CRS and
HIPEC did not differ from resected patients without PC (median OS both from surgery and from initial diagnosis) (Table 3).

An optimal PCI cutoff for CRS and HIPEC is controversially discussed in the literature [8]. A large meta-analysis of 748 patients defined a PCI of 12 as an optimal PCI cutoff [39]. Other authors favor a lower PCI cutoff of ≤6 [29, 40]. We also observed a better OS in the group of patients with PCI ≤6, but PC recurrence rates showed to be independent of the PCI value: in both patient groups, 42.9% did not suffer from a PC recurrence within the follow-up period. Our results favor the idea that also patients with PCI >6 could possibly benefit from CRS and HIPEC due to the negative impact of PC on the quality of life.

There are clear limitations of this study, that is, the retrospective, not randomized analysis, the small number of patients that also prohibited a matching of the control group, and the short follow-up of only 2 years. Furthermore, all patients were treated at a single institution, limiting the generalizability of the results. On the other hand, we rigorously analyzed the postoperative course of the patients included in the study, implementing up-to-date measures for postoperative complications. Based on our data, we thus believe to be able to conclude that CRS and HIPEC with primary PC is a safe procedure that does not increase morbidity and mortality rates compared to non-PC patients with similar advanced gastric cancer (pT3–4, pN1–3, UICC III or higher), at least in our hospital setting. The finding of a high percentage of patients with PCI >6 not suffering from a PC recurrence is noteworthy. We hypothesize that quality of life is improved by CRS and HIPEC also in the PCI >6 group of patients, as the absence of PC even in the setting of a high overall recurrence rate of 85.6% could prevent typical complications of PC. Furthermore, the OS of patients with primary PC after CRS and HIPEC was not different from patients with advanced gastric cancer without PC. In conclusion, we found no increase in morbidity and mortality after CRS and HIPEC including patients with a PCI up to 12 compared to a similar advanced patient cohort without PC in our hospital setting while achieving a similar OS.

**Statement of Ethics**

The study was approved by the Ethics Committee of the Technological University of Dresden (BO-EK-431092020). All procedures performed in this study involving human participants were in accordance with the 1964 Declaration of Helsinki and its later amendments. All patients were given written informed consent to the operative procedures.

**Conflict of Interest Statement**

The authors have no conflicts of interest to declare.

**Funding Sources**

This study was performed without funding by any sponsor.

**Author Contributions**

D.E. Stange and F. Merboth conceived of the presented idea. F. Merboth developed the theory and performed the computations. F. Merboth, S. Garcia, and J. v. Renesse performed data collection and analyzed the data, and F. Merboth wrote the manuscript. F. Merboth, S. Garcia, and J. v. Renesse performed data collection and analyzed the data, and F. Merboth wrote the manuscript. S. Garcia, J. v. Renesse, D.E. Stange, and F. Merboth contributed to the writing of this article and/or its online supplementary files. All authors discussed the results and contributed to the final manuscript.
