ABSTRACT

The nearby star $\alpha$ Oph (Ras Alhague) is a rapidly rotating A5IV star spinning at $\sim 89\%$ of its breakup velocity. This system has been imaged extensively by interferometric techniques, giving a precise geometric model of the star’s oblateness and the resulting temperature variation on the stellar surface. Fortuitously, $\alpha$ Oph has a previously known stellar companion, and characterization of the orbit provides an independent, dynamically based check of both the host star and the companion mass. Such measurements are crucial to constrain models of such rapidly rotating stars. In this study, we combine eight years of adaptive optics imaging data from the Palomar, AEOS, and CFHT telescopes to derive an improved, astrometric characterization of the companion orbit. We also use photometry from these observations to derive a model-based estimate of the companion mass. A fit was performed on the photocenter motion of this system to extract a component mass ratio. We find masses of $2.40^{+0.23}_{-0.37} M_\odot$ and $0.85^{+0.06}_{-0.04} M_\odot$ for $\alpha$ Oph A and $\alpha$ Oph B, respectively. Previous orbital studies of this system found a mass too high for this system, inconsistent with stellar evolutionary calculations. Our measurements of the host star mass are more consistent with these evolutionary calculations, but with slightly higher uncertainties. In addition to the dynamically derived masses, we use $\textit{IHK}$ photometry to derive a model-based mass for $\alpha$ Oph B, of $0.77 \pm 0.05 M_\odot$ marginally consistent with the dynamical masses derived from our orbit. Our model fits predict a periastron passage on 2012 April 19, with the two components having a 50 mas separation from 2012 March to May. A modest amount of interferometric and radial velocity data during this period could provide a mass determination of this star at the few percent level.

Key words: instrumentation: adaptive optics – methods: data analysis – stars: individual (HIP86032) – techniques: image processing

1. INTRODUCTION

Although the binary properties of solar-type stars (Duquennoy & Mayor 1991; Metchev & Hillenbrand 2009) and lower mass late-type stars (Fischer & Marcy 1992; Reid & Gizis 1997) are becoming increasingly well understood, studies of the higher end of the mass spectrum are crucial for a broader understanding of stellar multiplicity. Indeed, recent simulations suggest that A stars may possess a greater abundance of both stellar and planetary mass companions (Kratter et al. 2010; J. Crepp 2010, private communication). However, the multiplicity characteristics of these more massive stars have only recently started to be surveyed (Shatsky & Tokovinin 2002; Kouwenhoven et al. 2005), and more extensive surveys are underway to place limits on the nature of massive-star multiplicity. In recent years, high contrast imaging techniques (Oppenheimer & Hinkley 2009; Absil & Mawet 2010) such as adaptive optics (hereafter “AO”) have matured significantly, allowing these studies to proceed. The nearby (14.68 pc) A5IV star $\alpha$ Oph (Ras Alhague) has a well-known companion (Wagman 1946; Lippincott & Wagman 1966; Gatewood 2005) with a 8.62 yr period, well established over several decades of monitoring and first resolved by McCarthy (1983). But a fuller characterization of the companion has not been possible, and, aside from the period, the orbital parameters have been loosely constrained (Kamper et al. 1989; Augensen & Heintz 1992; Gatewood 2005).

Characterization of the binary nature of A-star systems becomes doubly interesting when the host stars are also rapidly
Boccaletti et al. (2001) mistakenly reported the position angle 243◦ measured west of north. Gatewood (2005) noticed the problem, but mistakenly assumed it was a quadrant problem and changed the value by 180◦. We use the correct measurement position angle of 243◦ (A. Boccaletti 2010, private communication).

Epochs 7 and 8 are comprised of visible AO measurements obtained from the 3.63 m AEOS telescope on Haleakala, Hawaii (Roberts & Neyman 2002; Roberts et al. 2005). Epochs 9 and 11 were obtained using “The Lyot Project” (Sivaramakrishnan et al. 2007; Hinkley et al. 2007, 2009; Leconte et al. 2010), a diffraction-limited classical Lyot coronagraph (Lyot 1939; Sivaramakrishnan et al. 2001) working in the infrared and recently decommissioned at AEOS.

The thirteenth epoch of observations of the α Oph system was obtained using a recently commissioned coronagraph integrated with an integral field spectrograph (IFS) spanning the J and H bands (1.06 μm–1.76 μm) on the 200 in Hale Telescope at Palomar Observatory (Hinkley et al. 2008, 2011). This instrument package, called “Project 1640” is mounted on the Palomar AO system (Dekany et al. 1998; Troy et al. 2000) and is a dedicated high contrast imaging instrument providing low resolution spectra (λ/Δλ)~30–60 with a lenslet-based IFS and Apodized-Pupil Lyot coronagraph (Sommer 2005), an improvement of the classical Lyot coronagraph (Sivaramakrishnan et al. 2001). Epoch 14 observations were made at the Canada–France–Hawaii Telescope (Rigaut et al. 1998). The observations comprising epochs 10, 12, and 15 were obtained with the Palomar AO system and the PHARO infrared camera (Hayward et al. 2001). Astrometric points from epochs 6 through 15 are shown in Figure 1. Visual orbit of the α Oph system. The solid line is the best-fit solution while the gray band shows the allowed orbits based on Monte Carlo sampling of the parameter uncertainties. The primary is located at (0,0) and the astrometric data from Table 1 are plotted with the positional uncertainties. East is left and north is up.

### Table 1

Table of Astrometry

Notes. (1) McCarthy (1983) and Kamper et al. (1989) provide one-dimensional speckle measurements, (2) Boccaletti et al. (2001), (3) Roberts & Neyman (2002), (4) Upper limit to orbit, (5) Sivaramakrishnan et al. (2007), (6) Hayward et al. (2001), (7) Hinkley et al. (2008, 2011), (8) Rigaut et al. (1998).
Figure 2. Examples of data taken at the three epochs listed at the upper left hand corner of each panel. The left and middle images were taken with a near-IR camera with a coronagraph at the AEOS telescope. The right hand panel is a single slice extracted from a data cube from the high contrast integral field spectrograph at Palomar Observatory (Hinkley et al. 2008, 2011). The companion, α Oph B, is marked with a white arrow in all three epochs, and is shown near apastron in the third panel.

Table 2

| Parameter                        | Value       |
|----------------------------------|-------------|
| Semi-major axis $a$ (mas)        | $427^{+20}_{-13}$ |
| Eccentricity                     | 0.92 ± 0.03 |
| Inclination (deg)                | 125±9       |
| $\omega$ (deg)                   | 162 ±14     |
| $\Omega$ (deg)                   | 232 ±9      |
| Period (days)                    | 3148.4 (fixed) |
| Epoch of periastron (JD)         | 2452888 ± 53 |

| From astrometric photocenter motion (using visual orbit above) |
|---------------------------------------------------------------|
| Mass ratio (primary/secondary)                                 | $2.76^{+0.43}_{-0.27}$ |
| Parallax (mas)                                                 | 69.1 (fixed) |
| Fixed proper motion: E, N (mas yr$^{-1}$)                      | 123.3, −227.0 |
| System mass ($M_\odot$)                                        | 3.25$^{+0.40}_{-0.35}$ |
| $\alpha$ Oph A ($M_\odot$)                                    | 2.40$^{+0.23}_{-0.37}$ |
| $\alpha$ Oph B ($M_\odot$)                                    | 0.85$^{+0.06}_{-0.04}$ |

Figure 3. Relative photocenter positions of α Oph from MAP observations (Gatewood 1987) reported by Gatewood (2005) after subtracting out the system proper motion and an estimate of the center of mass. With the orbit fit shown in Figure 1, the component mass ratio is obtained by fitting the photocenter motion shown here. Except for the period, which we fixed to 8.62 yr. The results of the error analysis can be found in Table 2.

3. ORBITAL CHARACTERIZATION

We fitted an orbit to the astrometric data in Table 1 including the speckle data from Kamper et al. (1989). We used both a Levenberg–Marquardt method (using IDL procedure MPFIT developed by C. Markwardt), and also the IDL routine AMOEBA (Press et al. 1992), arriving at the same global solution. Comparing our predicted astrometry with the data, we find a reduced $\chi^2$ of 0.7. The best-fit orbital elements can be found in Table 2, where we have fixed the quadrant of $\omega$ using the radial velocity data of Kamper et al. (1989). In order to calculate errors for the orbital elements, we carried out a Monte Carlo simulation, allowing all parameters to vary in the fitting

---

19 We needed to flip the signs on $x$, $y$ from this work to be consistent with other astrometry measurements.

20 http://cow.physics.wisc.edu/~craigm/idl/idl.html
motion and an estimate of the center of mass. Lastly, we had to assume a flux ratio at the effective wavelength of the MAP experiment Gatewood (1987), similar to an R-band filter. Based on multi-wavelength detections of the companion at J, H, and K bands, we have estimated an R-band flux ratio of 5.3 mag (factor of 130) assuming the companion is a mid/late K star (See Section 4.1). Using the results from the two analyses, we constrain the masses to be $2.40^{+0.23}_{-0.37} M_\odot$ and $0.85^{+0.06}_{-0.04} M_\odot$ for $\alpha$ Oph A and $\alpha$ Oph B, respectively. Table 2 contains the results of this orbital fitting, along with the full set of the fit parameters.

4. ANALYSIS

4.1. Companion Spectral Energy Distribution

Table 3 presents the broadband apparent magnitudes for $\alpha$ Oph B obtained with the PHARO infrared camera at Palomar, as well as the AEOS VisIm camera. The spectral energy distribution for $\alpha$ Oph B is shown in Figure 4, accounting for the system’s 0.834 ± 0.024 distance modulus (Gatewood 2005). The broadband magnitudes listed in Table 3 are the result of a simultaneous photometric fit to each binary component which returns position angle, relative separation, as well as relative brightnesses. Figure 4 shows $I$-, $J$-, $H$-, Br$\gamma$, and $K$-band photometry. Also shown are broadband $J$- and $H$-band photometric values obtained with the Project 1640 IFS at Palomar Observatory. The Project 1640 observations were calibrated using reference star spectra obtained from the IRTF spectral library (Cushing et al. 2005; Rayner et al. 2009) in the same manner as described in Hinkley et al. (2010). However, these observations were gathered during the first light observations with this new instrument, and hence the calibration data set was obtained before a full understanding of an effective calibration process was mature.

Also shown in Figure 4 are theoretical broadband $I$-, $J$-, $H$-, and $K$-band fluxes based on the models of Siess et al. (2000). The curves in Figure 4 are interpolations between these values. At a spectral resolution of 30–60, late-G to early-M star spectra are very similar, preventing robust discrimination between them. Rather than plotting template spectra over the data for comparison, we have instead chosen to use these model-based interpolations with this new instrument, and hence the calibration data set was obtained before a full understanding of an effective calibration process was mature.

Note that these values are affected by orbital degeneracies since we have not incorporated any surface or orbital velocities into the estimate. However, because the primary spin geometry is nearly edge-on, these degeneracies do not matter much. We find that the mutual angle of inclination is $\Phi = 36^\circ \pm 6^\circ$ (or $\Phi = 144^\circ \pm 6^\circ$ for the opposite spin polarity). Interestingly, this lies close to the predicted peak inclination (40°) that arises from Kozai cycles in the context of an inner short-period binary (Fabrycky & Tremaine 2007), echoing findings of Mutsterpaugh et al. (2008).

5. DISCUSSION AND CONCLUSIONS

We have obtained an orbital fit for the $\alpha$ Oph system and derived component masses of $2.40^{+0.23}_{-0.37}$ and $0.85^{+0.06}_{-0.04} M_\odot$ for $\alpha$ Oph A and $\alpha$ Oph B, respectively. Our estimation of the mass of $\alpha$ Oph A is lower than the $2.84 \pm 0.19 M_\odot$ value percent level. Due to the aforementioned uncertainties in the calibration of the Palomar Project 1640 photometry, only the Palomar PHARO data and the AEOS $I$-band data were used in the fit. Figure 4 also shows a curve corresponding to the dynamical best-fit mass value of 0.85 $M_\odot$, as well as a curve corresponding to 0.65 $M_\odot$ for reference. Comparing our derived near-infrared ($J-H$) and ($H-K$) colors with those documented in Bessell & Brett (1988) put the spectral type of the companion between a K5V and a K7V.
quoted by Gatewood (2005). However, our Monte Carlo approach yields more conservative estimates of the uncertainties, overlapping with other works. Specifically, the $2.1 \, M_\odot$ value for $\alpha$ Oph A quoted by Zhao et al. (2009) and measured using an H-R diagram overlaid with isochrones is allowed at this work’s 1σ level, while it is only allowed at the 3.5σ level in the Gatewood (2005) study. Our work demonstrates that, especially with a high eccentricity orbit, careful estimates of stellar parameters are essential.

We anticipate that this dynamical estimation of the mass of $\alpha$ Oph A will aid forthcoming studies focused not only on modeling the rapid rotation of $\alpha$ Oph A, but also of the host star’s asteroseismological properties (Monnier et al. 2010). The mass value derived here may help to distinguish between models that assume solid-body rotation of the star or have some degree of differential rotation beneath the photosphere.

Moreover, we have compiled the most complete set of photometric data yet for $\alpha$ Oph B from several observing programs to obtain an estimate of the companion mass through the use of theoretical models. The $0.77 \pm 0.05 \, M_\odot$ estimation of the companion mass derived photometrically is marginally consistent with the $0.85^{+0.06}_{-0.04} \, M_\odot$ value for $\alpha$ Oph B. Our infrared colors and the corresponding best-fit mass–luminosity curve are consistent with a mid/late-K dwarf classification for the companion.

Finally, based on our fit, $\alpha$ Oph B will be passing through periastron on 2012 April 19, with an uncertainty on this date of ±53 days. However, the separation between the two objects should be ~50 mas from 2012 March 24 to 2012 May 21. Such a separation will be ideal for existing state-of-the-art interferometers such as the CHARA Array or the Very Large Telescope Interferometer. Intensive astrometric monitoring of this system and new radial velocity observations, especially during periastron, can help to constrain the mass of $\alpha$ Oph A to within a few percent.

This work was performed in part under contract with the California Institute of Technology (Caltech) funded by NASA through the Sagan Fellowship Program. The Lyot Project is based upon work supported by the National Science Foundation under Grant Nos. AST-0804417, 0334916, 0215793, and 0520822. The Lyot Project gratefully acknowledges the support of the US Air Force and NSF in creating the special Advanced Technologies and Instrumentation opportunity that provides access to the AEOS telescope. The Lyot Project is also grateful to the Cordelia Corporation, Hilary and Ethel Lipsitz, the Vincent Astor Fund, Judy Vale, and an anonymous donor who initiated the project. A portion of the research in this paper was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration. Thanks also to Anthony Boccaletti for clarification of his epoch of the $\alpha$ Oph astrometry. We thank Willie Torres for help checking the notation of our orbital elements, and also to the anonymous referee for several helpful comments. J.D.M. gratefully acknowledges support from the National Science Foundation under Grant AST-0707927.
