Abstract
Stabilization of nano-oxide suspensions is a very important process. Nowadays, synthetic polymers are used to increase stability of the colloidal systems. However, this solution is not ecological and incompatible with the principles of green chemistry. Instead of synthetic polymers, their natural counterparts can be used. Herein, we present the use of natural bioactive polysaccharide—fucoidan as a stabilizer of nano-zinc(II) and nano-titanium(IV) oxide suspensions. These two oxides are commercially available and are widely used in the cosmetic and pharmaceutical industries. The turbidimetric studies (Turbiscan Lab) showed that the addition of fucoidan leads to the increase of stability and that the effect depends on the polymer concentration. To fully describe the systems’ stability, the adsorption (UV–Vis and FT-IR/PAS) and the electrokinetic properties (zeta potential and surface charge density) were studied. The obtained results indicate that fucoidan adsorbs by the electrostatic and non-electrostatic interactions on the used oxides forming the tight adsorption layer. The following paper thoroughly explains the stabilization mechanism of fucoidan toward the nano-oxide suspensions. Moreover, the presented results could be useful in the preparation of new cosmetic and pharmaceutical products containing nano-oxides.

Keywords Turbiscan · TSI · ZnO · TiO₂ · Nano-oxides

Introduction
Nanotechnology is one of the most dynamically developing fields of science. Even though this term means very little to an average consumer, it is incredibly profitable from the manufacturers’ point of view. Therefore, many technological giants spends billions of USD every year for their R&D departments. Taking this into account, the experiments on nanoparticles are not only commercially important, but also scientifically. While new products are developed, and their new properties are appreciated, the science behind this is very limited. Nowadays, a great part of cosmetic and pharmaceutical formulations is based on the different nanomaterials (Nohynek et al. 2008; Raj et al. 2012). In the case of colloidal suspensions, which are extensively used in the industry, the main problem is their limited stability. The colloidal suspensions composed of oxide particles and an aqueous medium is susceptible to aggregation, agglomeration and sedimentation (Chabni et al. 2011). To counteract the systems instability, the addition of different substances is used. Among others, the most often, polymers are used to this purpose (Pefferkorn 1995; Pettersson et al. 2000; Farrokhpour 2009). The problem with the use of the synthetic...
polymer is their limited applicability due to the health concerns. Moreover, in many cases, they are environmentally unfriendly and can cause some negative changes in the ecosystem (Mülhaupt 2013). A solution to this problem is the use of natural macromolecular compounds such as polysaccharides (Rinaudo 2007; Bouyer et al. 2012). The marine polysaccharides obtained from the different kinds of algae and other aquatic species are of a great interest (Laurienzo 2010; Ruocco et al. 2016). Fucoidan is one of the marine polysaccharides that is obtained from the brown algae and other brown seaweeds (Wijesekara et al. 2011). It is an anionic polysaccharide composed of L-fucose rings connected by the glycosidic bond. The negative charge of the polymer chains comes from the presence of the sulfate groups. Moreover, other functional groups such as carboxylic group can be found in the polymer structure (Li et al. 2008). Fucoidan can be used as a stabilizer of colloidal suspensions (Matusiak et al. 2020). Furthermore, it is used in different formulations due to its bioactive properties (Zayed et al. 2020).

Stabilization of the colloidal systems is a very sophisticated process that depends on many factors (Tadros 2011). The addition of the polymer to the studied system leads to stabilization due to the steric and/or depletion effects (Zhulina et al. 1990). Steric stabilization occurs when the polymer adsorbs on the solid surface. In such case, the formed polymer layer leads to the lower contact between the solid particles, which results in the increase of stability (Tadros 2013). When the used polymer is characterized by an ionic nature, the term steric stabilization changes to the electrosteric one since the new charge factor is present in the system (Fritz et al. 2002). On the other hand, if the polymer does not adsorb on the solid surface, but its chains are located between the solid particles preventing from their aggregation, the depletion stabilization is observed (Semenov and Shvets 2015). Since this process depends on many variables, it requires the comprehensive approach. Therefore, the adsorption of the polymer on the surface of the studies oxides and the electrokinetic studies of the used system are necessary to describe the stabilization mechanisms.

The aim of this study was to investigate stability of two nano-oxides suspensions: ZnO and TiO₂ in the absence and presence of fucoidan. These oxides are commercially used in different cosmetic and pharmaceutical formulations, for example in ointments, creams, pastes, suspensions and lotions (Weir et al. 2012; Kołodziejczak-Radzimska and Jesionowski 2014). There is no information available on stabilization of the oxides used in the cosmetic products using fucoidan as a stabilizer. Therefore, this paper presents new, valuable and detailed information regarding stabilization of the fucoidan/ZnO and the fucoidan/TiO₂ nanosized suspensions. To describe the stabilization mechanisms, the adsorption and the electrokinetic studies (zeta potential and surface charge density) were carried out. Based on the obtained results, it was established that fucoidan adsorbs on the studies nano-oxides, and strongly influences stability and the electrokinetic properties of the systems. Moreover, using FT-IR/PAS and UV–Vis adsorption studies as well as the electrokinetic one, it was shown that the adsorption of fucoidan is not only electrostatic, but its mechanism can be also considered non-electrostatic. The stability of the studied systems increased with the fucoidan concentration and was higher for the TiO₂ suspension. The obtained results represent better perspective on the use of natural polymers as potential green stabilizers of the colloidal systems.

### Materials

Two different nano-sized oxides were used as adsorbents: zinc(II) oxide (ZnO, zincite, CAS 1314-13-2) and titanium(IV) oxide (TiO₂, anatase, CAS 1317-70-0). Both nano-oxides are commercially available and were obtained from Alfa Aesar (Thermo Fisher Scientific). They were washed with ultrapure water using the laboratory magnetic stirrer until the conductivity of the supernatants was below 2 μS/cm. Then they were dried in a laboratory oven (100 °C) and then they were used in the further experiments. According to the producer information, the size of primary particles was estimated to 40–100 nm and 32 nm for ZnO and TiO₂, respectively. The actual size of the particles in suspensions was obtained using the DLS measurements (ZetaSizer ZS90, Malvern). The size distribution is shown as the changes of relative intensity of light scattered by the nanoparticles (Y axis) versus particle size (X axis). It equalled 145 nm for ZnO and 114 nm for TiO₂ (Fig. 1). The specific surface area was also investigated using the low temperature adsorption–desorption studies (ASAP BET, Micrometrics). Zinc(II) oxide was characterized with lower specific surface area.

![Fig. 1](image-url) The particle size distribution of the two used nano-oxides (ZnO and TiO₂) obtained from DLS measurements.
area \(S_{\text{BET}}\) of 13.6 m\(^2\)/g, whereas the \(S_{\text{BET}}\) of TiO\(_2\) equalled 50.3 m\(^2\)/g. The purity of the used nano-oxides was confirmed using the X-ray fluorescence spectrometry (Epsilon 5, PANalytical) showing that both contained over 99.2 and 98.6\% of zinc(II) oxide and titanium(IV) oxide, respectively.

Commercially available fucoidan (Carbosynth Ltd., CAS 9072-19-9) was used as an adsorbate. Its molecular weight was estimated using the static light scattering method and equalled 1730 kDa. The sulphate content was also investigated. The conducted analysis showed that the polymer chain contained 5.96\% of sulfate groups. Further information regarding the polymer characterization, molecular weight and sulfate content, FT-IR confirmation, altogether with the detailed measurements conditions were published in the previous work (Matusiak et al. 2020).

Other reagents: sodium chloride, sulfuric acid, hydrochloric acid and sodium hydroxide were purchased from POCH Gliwice (Avantor Performance Materials Poland).

Methods

Adsorption

To quantify the adsorption of fucoidan (FD) on the ZnO and TiO\(_2\) surfaces, the colorimetric method was used (Albalas-meh et al. 2013). The adsorption experiments were prepared as follows: to 10 cm\(^3\) of the polymer solution with various concentrations (50–500 ppm) containing ultrapure water and sodium chloride as a background electrolyte (0.01 mol/dm\(^3\)), 0.1 g of the nano-oxide powder was added. Then pH was verified, and the sealed flasks were placed in a thermostatic bath with linear shaking (25 °C, 120 rpm) for 15 h to achieve the adsorption–desorption equilibrium. Then, the contents of the flasks were transferred to the test tubes and centrifuged twice (4000 rpm) to separate the solid particles from the liquid. The obtained supernatants were used in further adsorption studies. 0.5 cm\(^3\) of each supernatant was placed in a glass tube, then 0.5 cm\(^3\) of the ultrapure water and 3 cm\(^3\) 96\% sulfuric acid were added. The mixture was gently mixed and cooled to the room temperature. Then the obtained mixtures were analyzed in UV–Vis spectrophotometer (Cary 100, Varian Instruments) with ultrapure water as a reference. The absorbance was measured at 315 nm. The adsorption values were calculated from the earlier prepared calibration curves. The adsorption measurements were conducted at least in triplicate and the average value was used.

FT-IR/PAS spectroscopy

Fourier transformed photoacoustic infrared spectra (FT-IR/PAS) of the examined samples were recorded by means of Bio-Rad Excalibur FT-IR 3000 MX spectrometer over the 4000–400 cm\(^{-1}\) range at room temperature, resolution 4 cm\(^{-1}\), mirror velocity 2.5 kHz and maximum source aperture, using MTEC Model 300 photoacoustic cell. Dry helium was used to purge the photoacoustic cell before data collection. The spectra were normalized by computing the ratio of a sample spectrum to the spectrum of a MTEC carbon black standard. A stainless steel cup (diameter 10 mm) was filled with sample (thickness < 6 mm) and interferograms of 1024 scans were averaged for the spectrum, providing good signal-to-noise (S/N) ratio. No smoothing functions were used. All spectral measurements were performed at least in triplicate.

Stability

Turbiscan LAB (Formulaction) was used to study stability of the prepared suspensions. This device is used for a fast and sensitive identification of the destabilization mechanisms in a controlled temperature conditions. According to the manufacturer, the instrument detects stability evolution at an early stage and also quantifies the global formula alteration with TSI (turbiscan stability index) scale. The principle of the measurement is based on the turbidimetric method. The laser light passing through the studied system is absorbed and/or reflected and then the signal is collected by the detector. The more detailed description of this method can be found in the previously published work (Grządka et al. 2020). The suspensions were prepared by the addition of 0.005 g of solid sample to the sodium chloride solution (0.01 mol/dm\(^3\)). Afterward, they were treated with the ultrasounds for 30 s to disperse the solid particles in a liquid medium. Then, the specific amount of fucoidan was added to obtain the desired concentration (100 and 500 ppm) and pH of the suspension was checked. The final sample volume equalled 10 cm\(^3\). Such sample was placed in the chamber of Turbiscan Lab device. The changes of the studied system stability were recorded for 15 h, every 1 h. The changes in the system’s stability were shown as a change of the turbiscan stability index (TSI) values over time. The calculation of the TSI is based on the laser backscattering of the sample and the number of scans (Kang et al. 2011). The TSI values changes from 0 (for the most stable systems) to 100 (for the least stable systems). In other words, the higher the TSI, the lower will be the stability.

Electrokinetic properties

The zeta potential (ZP) and the surface charge density (\(\sigma\)) experiments of the studied systems were also carried out. The zeta potential calculation is based on the electrophoretic mobility of the studied system using the Smoluchowski equation (Sze et al. 2003). The used device was a ZetaSizer Nano ZS90 (Malvern). The samples were prepared by the
The addition of the solid sample (0.01 g) to 100 cm³ of the solution containing the background electrolyte (NaCl, 0.01 mol/dm³) and the polymer. The samples were then treated by the ultrasounds for 3 min. Fucoidan was added after the ultrasound treatment to avoid the polymer chains degradation. pH of the studied suspensions was adjusted using HCl (0.01 mol dm⁻³) or NaOH HCl (0.01 mol dm⁻³), respectively. The surface charge density (σ) of the nano-oxides before and after the addition of fucoidan was determined by the potentiometric titration. The σ was calculated automatically by the Miar_t software developed by Władysław Janusz (commercially unavailable). The suspensions were prepared by the addition of the solid sample (based on the specific surface area of the oxide, so that the available surface of the oxide added to the suspension equalled 20 m²/g) to the 50 cm³ of background electrolyte solution (NaCl, 0.01 mol dm⁻³) containing the polymer. The suspensions were placed in a thermostated vessel and were titrated with the NaOH solution (0.1 mol dm⁻³) in the pH range 3–11 (Matusiak and Grządka 2020).

Results and discussion

The adsorption of the polysaccharides on the solid surface is usually based on the electrostatic interactions between the oppositely charged species. Figure 2 shows the comparison of the adsorption of fucoidan on the surface of the two used nano-oxides: ZnO and TiO₂.

As one can see fucoidan can adsorb on both oxides, but the higher surface coverage is observed in the case of zinc oxide, whereas lower in the case of TiO₂. It could be explained by the fact that those two oxides possess different surface properties. Based on the electrokinetic data (further explained in the next parts of the manuscript), the surface of ZnO in its natural pH is characterized by the positive charge, whereas the TiO₂ surface is neutral or only slightly positively charged. Because fucoidan is an anionic polysaccharide, its higher adsorption on the surface of ZnO is governed by the electrostatic interactions between the polymer and the surface. However, in the case of the FD/TiO₂ system, the observed adsorption is lower than in the FD/ZnO system. Considering the fact, that the TiO₂ surface in its natural pH is not charged (or charged in a very small extent) other adsorption mechanisms such as non-electrostatic interactions should be considered. Moreover, the decrease of the adsorption of fucoidan on the surface of these two oxides with increasing pH also suggests the partial contribution of the electrostatic mechanism in the adsorption of the polysaccharide on the solid surfaces (Fig. 3).

As stated before, the non-electrostatic interactions should not be neglected. Since the titania surface in its natural pH is barely charged, the most probable mechanism of the fucoidan adsorption except for the electrostatic interactions on the TiO₂ surface would be hydrogen bonding. The most likely adsorption mechanism in this system is formation of hydrogen bonds between hydroxyl groups from the fucoidan chain and the hydroxyl ones from the surface of the adsorbent. As one can see, the adsorption barely changes in pH 6 and 7, but the more significant decrease of the adsorption of fucoidan on TiO₂ is observed in pH 8 and 9, where the surface is more negatively charged. The adsorption of fucoidan on the ZnO and TiO₂ surfaces is most likely electrostatic one, whereas the non-electrostatic interactions can also play a significant role. To confirm these findings, the FT-IR/PAS analysis was carried out.

The confirmation of the non-electrostatic adsorption mechanism was found in the FT-IR studies (Fig. 4). In the case of the pre-adsorbed spectra of ZnO and TiO₂, a specific band at ~ 3690 cm⁻¹ are present. This band is the representation of the isolated –OH groups that could be found on the solid surface. After the adsorption they disappear, which could confirm the formation of the hydrogen bonds between

**Fig. 2** The comparison of the adsorption of fucoidan on the ZnO and TiO₂ surface; natural pH: 6.5–7.0 for ZnO and 6–6.5 for TiO₂

![Image](https://example.com/image2.png)

**Fig. 3** The influence of pH on the adsorption of fucoidan (200 ppm) on ZnO and TiO₂
the ZnO and TiO2 surfaces and the fucoidan chains. Therefore, the combination of the electrostatic interactions and the hydrogen bonding is responsible for the adsorption of FD on the studied oxides. As it was mentioned, Fourier-transform photoacoustic infrared spectroscopy (FT-IR/PAS) was used as a complementary technique for confirmation of fucoidan adsorption on the ZnO and TiO2 surface. Figure 4 shows the spectra of pure FD, post-adsorption and pre-adsorption (pure ZnO and TiO2). The spectrum of pure FD exhibited a broad band at ~ 3400 cm−1 and a band at 1630 cm−1 assigned to the –OH and H2O stretching vibrations. The bands within 2985–2882 cm−1 and at 1416 cm−1 are assigned to the C–H stretching in pyranoid ring (Chale-Dzul et al. 2015). The band at ~ 1373 cm−1 is assigned to C–H deformation vibrations. The band at 1730 cm−1 is associated with C=O stretching, 1603 cm−1 is assigned to the dissociated carboxylic groups COO– stretching. The bands at 1150, 1083 and 1030 cm−1 are responsible for C–O stretching and a band at 1246 cm−1 indicates S=O asymmetric stretching of sulfate groups (Barbosa et al. 2019). Analyzing the spectra of the ZnO and TiO2 before and after FD adsorption (Fig. 4), it can be observed that fucoidan adsorbed on the oxides surface. In the spectra of ZnO/TiO2 + FD, some new bands appear which are absent in the spectra of pure oxides. These are the bands in the range of CH groups vibration (2985–2882 cm−1 and at 1416 cm−1), the shoulder at 1603 cm−1 (COO– stretching) and the bands of C–O stretching (1150–1030 cm−1).

The changes of the surface morphology of ZnO and TiO2 before and after the adsorption were observed on the SEM micrographs (Fig. 5).

As one can see, the adsorption of fucoidan leads to the formation of the larger structures due to the agglomeration of the solid particles by the polymer chains. Before the adsorption, the disordered powder is observed, whereas in the presence of fucoidan, more defined architecture is created.

As previously mentioned, stabilization of the nano-oxide suspensions can be achieved successfully using the addition of macromolecular substances to the system (Matusiak et al. 2020; Grządka and Matusiak 2020). Figure 6a shows the changes in the turbiscan stability index (TSI) of the TiO2 suspension over time before and after the addition of different concentrations of FD.

As one can see, the addition of the polymer causes the decrease of the TSI values which corresponds to the increasing stability. Moreover, stability of the FD/TiO2 system increases with the increasing concentration of the used polymer. The mechanism of stabilization depends on the fact whether the used polymer adsorbs on the solid surface, or not. Since it was previously established that fucoidan adsorbs on the TiO2 surface the most probable stabilization mechanism is the electrosteric one. In such case, the negatively charged fucoidan chains adsorb on the solid particles of titanium dioxide. During this process, the solid particles are covered by the negatively charged polymer layer. According to the DLVO theory, stability of the colloidal system depends on the sum of the repulsion and attraction forces (Tadros 2010). Such hard spheres with the soft outer layers are stabilized by the electrostatic repulsions. Moreover, because the available adsorption space on the solid surface is limited, the increasing polymer concentration, except for the steric arrangements of the polymer chains, causes the saturation of the surface by the polymer chains. When the fucoidan concentration is low, its chains adsorb in rather flat
conformations. When the concentration increases, the rearrangement is observed, and more developed structures rich in loops and tails are formed (Matusiak et al. 2020). When the solid surface is saturated with the polymer chains, the rearrangement is no longer possible. Then the non-adsorbed polymer chains are also located between the FD-covered TiO$_2$ particles. The outcome of their presence between the solid particles can additionally stabilize the system. This phenomenon is called depletion stabilization and it is a consequence of the presence of the non-adsorbed polymer chains located in the bulk of the system (Semenov and Shvets 2015; Kim et al. 2015).

Similar, but less spectacular effect of the fucoidan addition on stability of the ZnO suspensions was observed (Fig. 6b). First of all, the TSI of pure ZnO is lower on contrary to the pure TiO$_2$. This observation shows that the ZnO suspensions are more stable over time without any additives. The addition of 100 ppm of fucoidan to the suspensions
leads to the small decrease of the TSI in the first 6 h of the experiments, and rather insignificant increase after that time. This is most likely because 100 ppm of FD is not sufficient to uphold stability of the ZnO suspensions for the longer period of time. However, the increase of the fucoidan concentration to 500 ppm leads to the increase of stability of the system. As well as in the case of the FD/TiO₂ system, the reason behind this phenomenon is the electrosteric stabilization of the zinc oxide particles.

The electrokinetic properties such as electrokinetic (zeta) potential (ZP) and the surface charge density (σ) provide additional information about the adsorption and stability of the studied systems. Two different values characterizing the electrical double layer (EDL) can be obtained based on the analysis of the zeta potential and the surface charge density. These are the isoelectric point (pHIEP) and the point of zero charge (pHpzc). The isoelectric point is pH where the zeta potential equals zero. In this specific point, the studied colloidal system is the least stable due to the absence of the repulsive forces between the present particles. Another valuable information that can be obtained from the electrokinetic data is the point of zero charge. The pH_pzc characterizes pH in which the number of the positively charged surface groups equals the number of the negatively charged ones. In other words, it is the point where the concentration of the groups bearing the positive charge is the same as the concentration of the negatively charged groups. As one can see, these two values describe different regions of the electrical double layer. pHIEP is used to characterize the diffused part of the EDL (where the zeta potential is measured), whereas pH_pzc describes the compact part of the EDL that is closer to the particles surface. Figure 7a shows the changes in the zeta potential and the surface charge of ZnO in the absence and presence of fucoidan.

As one can see, pHIEP of ZnO is between pH = 8 and 8.5 and pH_pzc of this oxide is also close to those values, which agrees with the literature data (Kosmulski 2020). It means that below these points, the surface of ZnO is positively charged and above them it is negatively charged. The addition of fucoidan to the ZnO suspension changes the electrokinetic properties of the systems. It can be observed that the PZC shifts toward the lower pH values, while the IEP is not observed after the addition of the polymer. The adsorption of fucoidan on the ZnO surface causes the shift of the slipping plane toward the bulk of the solution, which in the end results in the decrease of the zeta potential. Moreover, the higher the concentration, the lower is the zeta potential. Except for the higher adsorption of the polymer, it should be mentioned that with the increasing fucoidan concentration the number of the negatively charged polymer groups also increases. This fact additionally influences the zeta potential value. On the other hand, zeta potential is a valuable tool used to describe stability of the studied colloidal systems. It was established that when the ZP is larger than ±30 mV, the studied systems can be considered as stable (Kumar and Dixit 2017). It can be observed that the ZP values after the addition of fucoidan oscillate around −25 mV for 1 ppm of FD, and −35 mV for 10 ppm of fucoidan. This fact once again confirms that the addition of FD stabilizes the ZnO suspensions.

Figure 7b shows the changes of the zeta potential and the surface charge in the FD/TiO₂ system. The isoelectric point (pHIEP) of pure TiO₂ equals 6, whereas the point of zero charge (pHpzc) of this oxide is close to 6. Therefore, the TiO₂ surface is positively charged in pH < 6 and starts bearing negative charge in pH > 6. As it was previously mentioned in the case of this system, the non-electrostatic mechanism of adsorption is possible. The addition of FD to the TiO₂ suspension does not shift the PZC and lowers the surface charge only in a very small extent. This also confirms the theory that FD adsorb on the TiO₂ surface also by the non-electrostatic interactions. As far as the zeta potential
is discussed, the addition of FD leads to the decrease of the ZP of the studied systems. The explanation of this fact is the increasing number of the negatively charged fucoidan groups gathering in the diffused part of the electrical double layer. The higher the concentration, the more groups are delivered, and the consequence is the decrease of the zeta potential.

Conclusions

Based on the obtained results, it was shown that fucoidan adsors on the ZnO and TiO2 surfaces by the electrostatic and non-electrostatic interactions. It was also established that the addition of fucoidan to the studied suspensions leads to the increased stability due to the combination of the electrosteric and depletion effects. Moreover, stability was higher in the presence of higher fucoidan concentration (500 ppm), but the effect was more spectacular in the case of the FD/TiO2 system. The addition of fucoidan to the ZnO and TiO2 suspensions changes their electroskinetic properties. In the case of the zeta potential, the addition of FD leads to the decrease of ZP, which results from the combination of the adsorption of the polymer as well as the presence of the negatively charged groups in the electrical double layer.

The presented results explain the stabilization mechanism of fucoidan toward the nano-oxide suspensions. Furthermore, the obtained data could provide additional information useful in the processes of formulation of new different cosmetic and pharmaceutical products.
