Abstract

In a recent paper, Newman surveys the literature on power law spectra in evolution, self-organised criticality and presents a model of his own to arrive at a conclusion that self-organised criticality is not necessary for evolution. Not only did he miss a key model (Ecolab) that has a clear self-organised critical mechanism, but also Newman’s model exhibits the same mechanism that gives rise to power law behaviour as does Ecolab. Newman’s model is, in fact, a “mean field” approximation of a self-organised critical system.

In this paper, I have also implemented Newman’s model using the Ecolab software, removing the restriction that the number of species remains constant. It turns out that the requirement of constant species number is non-trivial, leading to a global coupling between species that is similar in effect to the species interactions seen in Ecolab. In fact, the model must self-organise to a state where the long time average of speciations balances that of the extinctions, otherwise the system either collapses or explodes.

In view of this, Newman’s model does not provide the hoped-for counter example to the presence of self-organised criticality in evolution, but does provide a simple, almost analytic model that can used to understand more intricate models such as Ecolab.

I. INTRODUCTION

Over the last five years, the notion that Biological Evolution is a self-organised critical phenomenon has gained currency, and in particular, has been championed by Bak [4] and Kauffman [5]. Self-organised critical phenomena are characterised by a frustration between two processes. The archetypical example is that of a sandpile, where the process of adding sand to a sand pile makes the slope of that pile steeper is opposed by the instability of the sandpile which works to make the sandpile flatter once the slope passes a critical angle. One of the the most obvious manifestations of criticality is a power law spectral behaviour, although criticality is by no means necessary for this power law behaviour to be manifest.

In a recent paper, Newman [1] surveys the field to conclude that the mechanism by which ecosystems are driven to criticality is not well understood, but that the evidence in the fossil record for power law spectra of extinction event size and species lifetimes is good. Solé et. al. [6] present the best evidence yet that these distributions are power laws. However, Newman missed an important model of evolution, Ecolab [2,3], that is more general than those surveyed, and gives us the best idea yet of how evolution could be a self-organised critical phenomenon.

Newman goes further to introduce his own model of evolution to make the point that the coevolutionary avalanches that all the other models (including Ecolab) exhibit are not necessary for the observed power law behaviour. He further claims that his model is not critically self-organised. However, the mechanism that leads to power law behaviour in Newman’s model is precisely the same as that in Ecolab, and that mechanism is of the nature of a frustration between two processes that characterises Bak’s sandpile model.

II. ECOLAB

In this section, we consider a model of evolution called Ecolab. Ecolab (perhaps unfortunately) is both the name of a model and a simulation system written by the author to implement that model. The ecology is described by a generalised Lotka-Volterra equation, which is perhaps the simplest ecological model to use.

\[ \dot{n}_i = r_i n_i + \sum_{j=1}^{n_{sp}} \beta_{ij} n_i n_j \]  

(1)

Here \( r \) is the difference between the birth rate and death rate for each species, in the absence of competition or symbiosis. \( \beta \) is the interaction term between species, with the diagonal terms referring to the species’ self limitation, which is related in a simple way to the carrying capacity \( K_i \) for that species in the environment by \( K_i = -r_i \beta_{ii} \). In the literature (eg Strobeck [7], Case [8]) the interaction terms are expressed in a normalised form, \( \alpha_{ij} = -K_i/r_i \beta_{ij} \), and \( \alpha_{ii} = 1 \) by definition. \( n \) is the species density.

These equations are simulated on a simulator called Ecolab. [9] The vectors \( n \) and \( r \) are stored as dynamic arrays, the size of which (i.e. the system dimension) can change in time.
A. Linear Stability Analysis

Linear analysis starts with the fixed point of equation (2)

\[ \dot{n} = -\beta^{-1}r, \]

where \( \dot{n} = 0 \). There is precisely one fixed point in the interior of the space of population densities (i.e. \( n \) such that \( n_i > 0 \)) provided that all components of \( \dot{n} \) are positive, giving rise to the following inequalities:

\[ \dot{n}_i = (\beta^{-1}r)_i > 0, \quad \forall i \]

This interior space is denoted \( \mathbb{R}_{+}^{n_{sp}} \) mathematically.

There may also be fixed points on the boundary of \( \mathbb{R}_{+}^{n_{sp}} \), where one or more components of \( n \) are zero (corresponding to an extinct species). This is because the subecology with the living species only (i.e. with the extinct species removed) is equivalent to the full system.

The stability of this point is related to the negative definiteness of derivative of \( \dot{n} \) at \( \dot{n} \). The components of the derivative are given by

\[ \frac{\partial \dot{n}_i}{\partial n_j} = \delta_{ij} \left( r_i + \sum_k \beta_{ik}n_k \right) + \beta_{ij}n_i \]

Substituting eq (2) gives

\[ \frac{\partial \dot{n}_i}{\partial n_j} \bigg|_{\dot{n}} = -\beta_{ij} (\beta^{-1}r)_i \]

Stability of the fixed point requires that this matrix should be negative definite. Since the \( (\beta^{-1}r)_i \) are all negative by virtue of (3), this is equivalent to \( \beta \) being negative definite, or equivalently, that its \( n_{sp} \) eigenvalues all have negative real part. Taken together with the inequalities (3), this implies that \( 2n_{sp} \) inequalities must be satisfied for the fixed point to be stable. This point was made by Strobeck [7], in a slightly different form. (Note that Strobeck implicitly assumes that \( \sum_i r_i \hat{n}_i/K_i > 0 \), so comes to the conclusion that \( 2n_{sp} - 1 \) conditions are required.) If one were to randomly pick coefficients for a Lotka-Volterra system, then it has a probability of \( 4^{-n_{sp}} \) of being stable, i.e. one expects ecosystems to become more unstable as the number of species increases [10].

B. Permanence

Whilst stability is a nice mathematical property, it has rather less relevance when it comes to real ecologies. For example the traditional predator-prey system studied by Lotka and Volterra has a limit cycle. The fixed point is decidedly unstable, yet the ecology is permanent in the sense that both species’ densities are larger than some threshold value for all time. Hofbauer et al. [11] and Law and Blackford [12] discuss the concept of permanence in Lotka-Volterra systems, which is the property that there is a compact absorbing set \( \mathcal{M} \subset \mathbb{R}_{+}^{n_{sp}} \) i.e.
once a trajectory of the system has entered \( M \), it remains in \( M \). They derive a sufficient condition for permanence due to Jansen \[13\] of the form:

\[
\sum_i p_i f_i(\hat{n}_B) = \sum_i p_i (r_i - \sum_j \beta_{ij} \hat{n}_{Bj}) > 0, \quad \exists p_i > 0
\] (6)

for every \( \hat{n}_B \) equilibrium points lying on the boundary (\( \hat{n}_{B_i} = 0 \), \( \exists i \)), provided the system is bounded (or equivalently dissipative). This condition is more general than stability of the equilibrium — the latter condition implies that a local neighbourhood of the equilibrium is an absorbing set. Also, the averaging property of Lotka-Volterra systems implies that the equilibrium must lie in the positive cone \( \mathbb{R}^{n_{sp}}_+ \). So (6) must still hold for permanence.

Consider the boundary points \( \hat{n}_B \) that are missing a single species \( i \). Then Jansen’s condition for these boundary points is

\[ r_i - \sum_j \beta_{ij} \hat{n}_{Bj} > 0. \] (7)

This set of conditions is linearly independent. Let the number of such boundary points be denoted by \( n_B \leq n_{sp} \). Then the set of conditions (6) will have rank \( n_B \leq \nu \leq n_{sp} \) (the number of linearly independent conditions, so the system has at most probability \( 2^{-n_{sp} - \nu} \) of satisfying Jansen’s permanence condition if the coefficients are chosen uniformly at random. As stability is also sufficient for permanence, the probability lies between \( 4^{-n_{sp}} \) and \( 2^{-n_{sp} - \nu} \).

Another rather important property is resistance to invasion. Consider a boundary equilibrium \( \hat{n}_B \). If it is proof against invasion from the missing species, then the full system cannot be permanent. For the boundary points that miss a single species, this implies that condition (6) is necessarily satisfied for permanence, along with (3). The probability of permanence is then bounded above by \( 2^{-n_{sp} - n_B} \).

The important point to take away from this section is that whilst a randomly selected ecology is more likely to be permanent than to have a stable equilibrium, the likelihood decreases exponentially with increase in species number.

C. Mutation

Adding mutation involves adding an additional operator to equation (1)

\[
\dot{n} = r \ast n + n \ast \beta n + \text{mutate}(\mu, r, n)
\] (8)

where \( \ast \) refers to elementwise multiplication. This operator extends the dimension of the whole system, so is rather unusual. It is not germane to the present argument what the precise form of \text{mutate} is, the interested reader is referred to the previous publications describing it \[2,3,9\]. Suffice it to say, that it adds new species according to a stochastic mechanism, and that we would expect that the criticality result to be robust with respect to changes of mutation algorithm employed.

---

1Boundedness is ensured in this model by choosing the \( \beta_{ij} \) such that \( \beta_{ij} + \beta_{ji} \leq 0, \forall i, j \). This precludes symbiosis, but does allow for unstable behaviour. See \[1] for a discussion of boundedness.
D. Self Organised Criticality

Let's consider what happens to the largest eigenvalue of $\beta$. Suppose initially, the system has a stable equilibrium, in which case all the eigenvalues have negative real part. As mutations are added to the system, the largest eigenvalue will increase towards zero. As it passes zero, the system destabilises, and the system will start to exhibit limit cycles or chaotic behaviour. As further mutations are added to the system, permanence is no longer satisfied, and an extinction event will occur. This will restore permanency to the system, and possibly even stability. So we have two frustrated processes opposed to each other, the first, mutation, which builds up ecosystem complexity, and the second being the trend to impermanency as ecosystem become more complex. This is analogous to the sand being added to the top of the pile, and the stability of the sandpile slope in Bak’s sandpile model.

III. THE NEWMAN MODEL

Newman has presented his model of evolution in a number of papers [14][15][1], and is largely equivalent to an earthquake model presented in [16][17]. In the biological context, the model has a fixed number of species, all of which feel an environmental stress, denoted by $\eta(t)$, which is random variate with distribution $p_{\text{stress}}(\eta)$. Each species has an individual threshold $x_i$, such that if $\eta > x_i$, species $i$ becomes extinct. These extinct species are then replaced by new species, with thresholds randomly assigned from some distribution $p_{\text{thresh}}(x)$. There is one further twist to the model, in that the threshold values are allowed to drift over time in order to prevent the model stagnating with every species having the maximum threshold.

The Ecolab software allows us to build a variant of this model that allows the number of species to vary over time. When the model was first implemented, the system underwent a “mutation catastrophe”, in which the number of species exploded. This is similar to what happens in the Ecolab model when the mutation rate is set too high. Normally, one would expect that the number of speciation events should be proportional to the number of species. However, this leads to an excess of speciation over extinctions.

The resolution of this conundrum is to require that the stress values $\eta$ be proportional to the number of species, i.e. $\eta = n_{\text{sp}}\eta'$, where $\eta'$ is drawn from some distribution $p_{\text{stress}}(\eta')$. The justification for making this assumption can be seen by considering a simplified model of Ecolab (called Ecolab--), described in the next section. Of course, in Newman’s original model, $n_{\text{sp}}$ is a constant, and so his model is consistent with this modification.

Wilke and Martinetz [18] examined a similar model, in which they label the mutation rate $g$, and consider finite $f$, rather than $f = 0$ as I do here. They too note the conundrum of exponential growth in species number, and resolve it by introducing an arbitrary logistic constraint. My argument is that the reason for this logistic constraint is that species must interact with each other, and the greater the number and strengths of these interactions, the greater the stresses are that are felt by the ecosystem.

It could be argued that the raison d’être of the Newman model is to study the effect of coherent extinction through exogenous causes. However, these will always give rise to stress distributions that are independent of species number. However, the stress distribution will ultimately be dominated by the term that does depend on the species number.
Once the stress values depend on species number, the system self-organises so that speciations and extinctions balance on average. A trace of $n_{sp}$ can be seen in Figure 1, and the distribution of lifetimes is seen in Figure 2. The peak in the curve at $\tau = 10$ is an artifact of the simulation, and should be ignored. The distribution actually has two regions, the inner one $10 \ll \tau \ll 10^3$ having a power law with exponent $\approx -1$, and the outer region $\tau \gg 10^3$ having exponent $\approx -2$. By running the experiment at different mutation rates, the lifetime $\lambda$ at which the distribution changed from $\tau^{-1}$ to $\tau^{-2}$ was found to be inversely proportional to the mutation rate.

In comparing the result of my variation with the original Newman model, it should be noted that the power law exponent in Newman’s original model is $-1$ out to a time $1/f$, and decays exponentially after that. In my version, the same power law exponent was observed out to $1/g$, and then appears to change to a faster power law decay, although the error bars are sufficiently large not to rule out an exponential decay. In each of these models, the lifetime $1/f$ or $1/g$ respectively is roughly the lifetime that a maximally fit organism (one with a maximal value $x_i$) can survive before succumbing to mutation pressures.

### IV. THE ECOLAB-- MODEL

In this section, we will consider a simplification of the Ecolab model where the interaction terms $\sum_j \beta_{ij} n_j$ are replaced by a random variate $\eta_i(t)$ from a suitable distribution:

$$\dot{n}_i = (r_i - \eta_i) n_i \quad (9)$$

Since $\eta_i$ is effectively a sum of a large number of independent quantities, its distribution will tend to be normal, and the deviation (controlling how large $\eta_i$ gets) will be proportional to $n_{sp}$, the connectance (proportion of nonzero elements in $\beta$) and the interaction strength. This is why stresses in the Newman model must be proportional to $n_{sp}$. When $\eta_i$ exceeds $r_i$ for any significant period of time, species $i$ becomes extinct. Since $\eta_i(t)$ is a continuous function of $n(t)$ which is itself a continuous function of $t$, there will be a correlation $\eta(t) \eta(t + \tau) > 0, \forall \tau < \tau_0, \exists \tau_0 > 0$. Equation (9) connects the full Ecolab model with the Newman model.

In order to make the analysis simpler, we assume that $n_i$ are real valued, rather than integers as in Ecolab. In order to detect when extinction happens, we take an arbitrary threshold $\sigma$, such that if $n_i < \sigma$, species $i$ is extinct.

### V. DISTRIBUTION OF SPECIES LIFETIMES

Figure 3 shows the distribution of species lifetimes (time from speciation to extinction) in the augmented Newman model. This figure is not normalised, as a power law $x^\alpha$ has an infinite integral. So the abscissa of the graph is not significant, but the slope is. The lines are fitted by linear regression. Authors often quote a correlation coefficient, however this is generally meaningless on a log-log plot. Even the value of the slope is meant to be an indication only, as the large relative error at high lifetime values can lead to significant errors in the computed slope.

Figure 3 shows the lifetime distribution for Ecolab which has a slope of $-2$ for lifetimes less than 100, but $-1$ for larger lifetimes. At still larger times ($\tau \gg 0.1/\mu$), the distribution
turns over, decaying exponentially. Previously published versions of this graph \[3\] only show
the smaller lifetime behaviour.

Consider now the probability \( p(\tau > t | x) \) that a species with threshold \( x \) will become extinct
after time \( t = \tau \) in the Newman model. Since time is discrete in this model, this is simply
the probability that the stress \( \eta \) does not exceed \( x \) for the first \( \tau \) steps:

\[
p(\tau > x | \eta) = \left[ \int_0^x p_{\text{stress}}(\eta) d\eta \right]^\tau.
\]

(10)

Now the distribution \( p(\tau > \tau) \) of species having lifetimes \( \tau \) is just the above quantity,
integrated over the distribution of thresholds:

\[
p(\tau > \tau) = \int p(\tau > \tau | x) dx
= \int p_{\text{thresh}}(x) \left[ \int_0^x p_{\text{stress}}(\eta) d\eta \right]^\tau
= \int_0^1 p_{\text{thresh}}(x) \xi^\tau d\xi dx d\xi
\]

(11)

where \( \xi = \int_0^x p_{\text{stress}}(\eta) d\eta \)

Assume the following inequalities hold:

\[
p_{\text{thresh}}(x) \leq K_1 p_{\text{stress}}(x), \quad \forall x
\geq K_0 p_{\text{stress}}(x) \quad \forall x < x_c, \exists x_c
\]

(12)

Without loss of generality, \( p_{\text{thresh}}(x) \) is taken to be the uniform distribution between 0 and
1, and is zero outside this interval. \( p_{\text{stress}}(x) \) is positive for all positive \( x \), with the large \( x \)
tail needed to establish power law behaviour \[15\]. In this case, the constants \( K_0 \) and \( K_1 \)
correspond to the inverses of the maximum and minimum of \( p_{\text{thresh}}(x) \) over the unit interval,
and \( x_c = 1 \). Let us introduce \( \xi_c = \int_0^{x_c} p_{\text{stress}}(x) dx \) as being the change of variable equivalent
of \( x_c \). In the case of uniform threshold distribution, and monotonic stress distribution, \( 1 - \xi_c \)
is the proportion of stress events that overwhelm the hardiest of species. The inverse of this
proportion is a time scale, above which the lifetime distribution must decay exponentially.
In order to observe power law behaviour, the stress distribution must be chosen so that
\( \xi_c \approx 1 \).

Substituting eq (12) into (11) generates the following inequality:

\[
K_0 \int_0^{\xi_c} p_{\text{stress}}(x) \xi^\tau \frac{dx}{d\xi} d\xi \leq p(\tau) \leq K_1 \int_0^1 p_{\text{stress}}(x) \xi^\tau \frac{dx}{d\xi} d\xi
\]

\[
K_0 \frac{\xi_c^\tau + 1}{\tau + 1} \leq p(\tau) \leq K_1 \frac{1}{\tau + 1},
\]

(13)

since \( p_{\text{stress}}(x) = d\xi/dx \) and where \( \xi_c = \int_0^{x_c} p_{\text{stress}}(x) dx \).

Now \( p(\tau) = p(\tau - 1) - p(\tau) \), so the following inequality is obtained:

\[
\frac{(K_0 \xi_c^\tau - K_1 \tau) + K_0 \xi_c^\tau}{\tau(\tau + 1)} \leq p(\tau) \leq \frac{(K_1 - K_0 \xi_c^\tau) \tau + K_1}{\tau(\tau + 1)}
\]

(14)
Assuming that $\tau \ll (1 - \xi_c)^{-1}$, $\xi_c^\tau = (1 + \tau(1 - \xi_c) + \cdots \approx 1$, this inequality may be simplified:

$$\frac{(K_0 - K_1)\tau + K_0}{\tau(\tau + 1)} \leq p(\tau) \leq \frac{(K_1 - K_0)\tau + K_1}{\tau(\tau + 1)} \quad (15)$$

This result indicates that there are two domains, the first being when $\tau < \frac{K_0}{K_1 - K_0}$, where the lifetimes distribution is a power law with exponent $-2$. This domain is more pronounced the closer $K_1$ is to $K_2$, i.e., the closer $p_{\text{thresh}}(x)$ is to $p_{\text{stress}}$. The other domain occurs when $\tau > \frac{K_1}{K_1 - K_0}$, where any power law will have an exponent less than $-1$. In between, there will be a transition between the two domains. This result is not terribly strong, as the inequality can also be satisfied by any distribution falling off faster than a power law. However, it does contradict the results of the Time Average Approximation theory of Sneppen and Newman [17] in the case of the Lorentzian distribution, where a power law with exponent 0 (i.e., a flat distribution) is predicted. Whilst a flat distribution is manifestly ridiculous, others are not. The TAA predicts a power law of $1/3$ for a power law stress distribution with exponent $-3/2$. Figure [4] shows the observed lifetime distribution in this case, and the distribution never flattens out more than $\tau^{-1}$.

Now let us turn our attention to the Ecolab-- model to see if similar relationship can be derived. In what follows, the species index $i$ is dropped. Integrating equation (9) gives us:

$$n(t) = n_0 e^{\int_0^t r - \eta(s)ds},$$

and taking logarithms gives:

$$\ln n(t) = \int_0^t r - \eta(s)ds,$$

since $n_0 = 1$ for all new species.

For the species to become extinct after time $t = \tau$, we require:

$$\int_0^\tau r - \eta(s)ds > \ln \sigma, \quad \forall t < \tau \quad (16)$$

Since time is discrete in this model, $\eta(s)$ is a piecewise constant function, therefore the integral can be replaced by a sum so that

$$\sum_{i=0}^{t-1} \eta_i < rt - \ln \sigma, \quad \forall t < \tau \quad (17)$$

Now inequality (17) defines a set $\mathcal{M} \subset \mathbb{R}^\tau$, and the probability of a species having lifetime greater than $\tau$ if its reproduction rate is $r$ is given by:

$$p(> \tau|r) = \int_{\mathcal{M}} \prod_{i=0}^{\tau-1} p_{\text{stress}}(\eta_i)d\eta_0d\eta_1 \cdots d\eta_{\tau-1} \quad (18)$$

Lets us first deal with sufficient conditions for inequality (17) to be satisfied, which are:
\[ \eta_i < r - \ln \sigma / \tau, \forall i \leq \tau \quad (19) \]
\[ < r, \text{ as } \sigma < 1 \quad (20) \]

Therefore a lower bound for \( p(> \tau | r) \) is
\[ p(> \tau | r) \geq \left[ \int_{-\infty}^{\tau} p_{\text{stress}}(\eta) d\eta \right]^\tau. \quad (21) \]

Now consider the following relation:
\[ n(t + 1) = (1 + r - \eta t)n(t) \]

For the species not to go extinct before \( t = \tau \), we require \( \eta t < 1 + r, \forall t \leq \tau \). Therefore,
\[ p(> \tau | r) \leq \left[ \int_{-\infty}^{(r+1)} p_{\text{stress}}(\eta) d\eta \right]^\tau. \quad (22) \]

Now find constants \( K_0 \) and \( K_1 \) so that
\[ K_0 p_{\text{stress}}(r) \leq p_r(r) \quad \forall r < r_c, \exists r_c, \leq K_1 p_{\text{stress}}(r + 1) \quad (23) \]
where \( p_r(r) \) is the probability distribution of reproduction rates. Since \( p(> \tau) = \int p_r(r)p(> \tau | r)dr \), we find:
\[ K_0 \int_{r_c}^{\tau} p_{\text{stress}}(r) \left[ \int_{-\infty}^{r} p_{\text{stress}}(\eta) d\eta \right]^\tau dr \leq p(> \tau) \leq K_1 \int p_{\text{stress}}(r + 1) \left[ \int_{-\infty}^{(r+1)} p_{\text{stress}}(\eta) d\eta \right]^\tau dr \]
\[ \frac{K_0 \rho_c^\tau}{\tau} \leq p(> \tau) \leq \frac{K_1}{\tau} \quad (24) \]

Now since \( p(\tau) = p(> \tau) - p(> \tau + 1) \),
\[ \frac{K_0 \rho_c^\tau}{\tau} - \frac{K_1}{\tau + 1} \leq p(\tau) \leq \frac{K_1}{\tau} - \frac{K_0 \rho_c^\tau}{\tau + 1} \quad (25) \]
\[ \frac{(K_0 \rho_c^\tau - K_1)\tau + K_0 \rho_c^\tau}{\tau(\tau + 1)} \leq p(\tau) \leq \frac{(K_1 - K_0 \rho_c^\tau)\tau + K_1}{\tau(\tau + 1)} \quad (26) \]

Again, like the Newman model, we have two domains of power law possible, an inner domain where the power law is \(-2\), and an outer domain where any power law is capped by \(-1\). This is what is seen in Figure 3.

VI. CONCLUSION

The Newman model owes its power law behaviour to much the same mechanism as does Ecolab, although the assumption of constant species number hides essential interspecies connections. Both models demonstrate a power law exponent near \(-2\) at small time scales, agreeing with the fossil record (after Sneppen et. al [19]), turning over into a gentler power law with exponent less than \(-1\) at larger times.
VII. ACKNOWLEDGEMENTS

The author wishes to thank the New South Wales Centre for Parallel Computing for use of their facilities to perform the computations for this paper. He also wishes to thank Mark Newman for comments on this paper.
