\textsuperscript{1}Guangdong Key Laboratory for Innovative Development and Utilization of Forest Plant Germplasm, State Key Laboratory for Conservation and Utilization of Subtropical Agro-Bioresources, Guangdong Province Research Center of Woody Forage Engineering Technology, Guangdong Research and Development Center of Modern Agriculture (Woody forage) Industrial Technology, South China Agricultural University, Guangzhou, China. \textsuperscript{2}College of Horticulture, South China Agricultural University, Guangzhou, China

Carbon dioxide (CO\textsubscript{2}) is a primary greenhouse gas and the main cause of global warming. Respiration from plant cells and microorganisms enables CO\textsubscript{2} to be produced during ensiling, a method of moist forage preservation applied worldwide. However, limited information is available regarding CO\textsubscript{2} emissions and mitigation during ensiling. Pyroligneous acid, a by-product of plant biomass pyrolysis, has a strong antibacterial capacity. To investigate CO\textsubscript{2} production and the influence of pyroligneous acid, fresh stylo, and rice straw were ensiled with or without 1% or 2% pyroligneous acid. Dynamics of the fermentation characteristics, CO\textsubscript{2} production, and bacterial communities during ensiling were analyzed. Pyroligneous acid increased the lactic acid content and decreased the weight losses, pH, ammonia-N content, butyric acid content, and coliform bacterial numbers (all \(P < 0.05\)). It also increased the relative abundance of \textit{Lactobacillus} and decreased the relative abundances of harmful bacteria such as \textit{Enterobacter} and \textit{Lachnoclostridium}. Adding pyrolytic acids reduced the gas production, especially of CO\textsubscript{2}. It also increased the relative abundances of CO\textsubscript{2}-producing bacterial genera and of genera with the potential for CO\textsubscript{2} fixation. In conclusion, adding pyroligneous acid improved the fermentation quality of the two silages. During ensiling, CO\textsubscript{2} production was correlated with bacterial community alterations. Using pyroligneous acid altered the bacterial community to reduce CO\textsubscript{2} production during ensiling. Given the large production and demand for silage worldwide, application of pyroligneous acid may be an effective method of mitigating global warming via CO\textsubscript{2} emissions.

Keywords: greenhouse gas, bacterial community, rice straw, stylo, fermentation quality
INTRODUCTION

Carbon dioxide (CO$_2$), a primary greenhouse gas, has received increasing attention in the past two decades and has become a priority because of its low-carbon and sustainable development worldwide (Ray et al., 2019). Approximately, 15% of anthropogenic greenhouse gas emissions are generated by animal husbandry production (Adegbeye et al., 2019). In recent years, considerable efforts have been made to reduce greenhouse gas emissions from animal husbandry production and manure treatment. Ensiling is a traditional method of conserving forage, and silage is used as an important nutrient feed source for ruminants worldwide (Dunière et al., 2013). In China, silage production is reported to exceed 280 million tons annually (Liu Z. et al., 2020) and is expected to further increase as the consumption of livestock products, such as milk and beef, increases. Metabolism of microorganisms and plant cells in silage leads to gas emissions, of which, CO$_2$ is the main gas produced. Cai et al. (1997) reported that after 60 days of fermentation, gas production exceeds 6.0 L/kg of fresh matter. However, McEniry et al. (2011) reported that CO$_2$ production mainly occurs in the early stages of ensiling, which constitutes > 60% of all the gas produced. CO$_2$ production during ensiling leads to nutrient loss from the silage and impacts the greenhouse effect, which affects the earth’s ecology. However, little research has been conducted on CO$_2$ emissions from silage.

Pyroligneous acid, a by-product of plant biomass pyrolysis, is a complex, condensed, crude, and highly oxygenated aqueous liquid fraction generated during wood charcoal production (Li et al., 2018). Pyroligneous acid consists of more than 200 compounds, including furan, organic acids, esters, phenols, alcohols, and pyran derivatives (Liu X. et al., 2020), and is recycled in many areas as an important commercially valuable resource. Pyroligneous acid is beneficial to agriculture and has been used as an insecticide, fertilizer, soil enhancer, animal feed supplement, and source of smoke flavoring for food (Zheng et al., 2020). Pyroligneous acid has strong antibacterial abilities owing to the presence of organic acids and phenolic compounds. Previous studies have shown that pyroligneous acid prevents the activities of microorganisms such as Pseudomonas, Escherichia, Staphylococcus, Aspergillus, and Candida, which are abundant during ensiling (de Souza Araújo et al., 2018; Suresh et al., 2019; Bai et al., 2020; Wu et al., 2020). However, the effects of pyroligneous acid on bacterial communities during ensiling remain unknown.

We hypothesized that adding pyroligneous acid during ensiling would reduce CO$_2$ production by altering the bacterial communities. We analyzed the fermentation quality, CO$_2$ production, and bacterial communities of fresh stylo and rice straw ensiled with pyroligneous acid.

MATERIALS AND METHODS

Silage Preparation

Stylo (Stylosanthes guianensis, CIAT 184) and rice (Oryza sativa L., Huahang 38) were planted without herbicide or fertilizer application in an experimental field of South China Agricultural University (23.24°N, 113.64°E, Guangzhou, China). Stylo (at the bloom stage) and rice straw (at the seed-harvesting stage) were harvested on August 08, 2020 and August 18, 2020, respectively. The two fresh materials were mixed and chopped to 1–2 cm by hand with a paper cutter, then treated with 1% or 2% pyroligneous acid based on fresh matter. Pyroligneous acid was obtained from blended wood waste and filtered through a 0.45-µm cellulose acetate membrane, similar to that reported by Zhang Y. et al. (2020). Approximately, 100 g of silage materials were packed and compressed manually into plastic-film bags (12 bags per treatment), sealed with a vacuum sealer, and stored indoors at 27–32°C. Silage samples from three bags were randomly collected after 3, 7, 14, and 30 days of fermentation, and the fermentation, gas production, and bacterial community parameters were determined.

Determination of Gas Production and CO$_2$ Concentration

The silage bag volume was measured in a 5000-ml beaker in a constant 25°C water bath. Gas production was then calculated using the difference in the volumes before and after silage (Cai et al., 1997). One microliter of the gas sample was collected with a microsyringe and injected into a gas chromatograph (Shimadzu GC-20A) to determine the CO$_2$ concentration. The CO$_2$ was separated on a molecular Sieve 5A and Porapak N column, with an oven temperature of 60°C for 5.5 min. The temperatures of the injector and detector were held at 100°C and 170°C, respectively. The quantitation limit of CO$_2$ in the gas chromatograph is 0.1% (v/v) using this method.

Fermentation Characteristics Analysis

The methods used to analyze the fermentation characteristics were similar to those used in our previous studies (Wang et al., 2018; He et al., 2020). Briefly, 20 g (including raw material and silage) of stylo and rice straw were taken randomly, soaked in 180 mL of sterile 0.9% saline for ~15 min, and serially diluted from 10$^{-1}$ to 10$^{-6}$ on a clean bench. Lactic acid bacteria (LAB) and coliform bacteria were cultured and estimated using deMan-Rogosa-Sharpe agar and violet red bile agar at 30°C for 2 days. Yeast and mold were cultured and determined on Rose-Bengal agar and violet red bile agar at 30°C for 2 days. Yeast and mold were cultured and determined on Rose-Bengal agar for 2 days at 28°C. The 20 g of each silage sample were homogenized with 180 mL of distilled water for 18 h at 4°C, then filtered through four layers of cheesecloth and filter paper. A glass-electrode pH meter was used to immediately measure the pH of this filtrate. Organic acid contents were determined using high-performance liquid chromatography as described by Wang et al. (2018). The dry matter content was measured immediately after drying the samples at 65°C using an electric dryer equipped with an air blower. The ammonia-N content was determined using a phenol-hypochlorite assay.

Bacterial Community Sequencing Analysis

The total bacterial DNA was extracted from the silage samples using a DNA kit (Omega Biotek, Norcross, GA,
The relative abundances of Leuconostoc in the rice straw silage, and adding 2% pyroligneous acid increased the Leuconostoc relative abundances. Frontiers in Microbiology | www.frontiersin.org

1

a 50-µL reaction mixture consisting of 1.5 µL of 5 µM of each primer, 1 µL KOD polymerase, 5 µL 10 × KOD buffer, 100 ng template DNA, and 5 µL of 2.5 mM dNTPs per the procedures of He et al. (2020). After purification and quantification, an Illumina HiSeq 2500 Sequencing System (Illumina, Inc., San Diego, CA, United States) was used for the PCR sequencing, and the raw sequences were analyzed as described by Wang et al. (2018). The bioinformatic data were examined via the free online platform at http://www.omicshare.com/tools by GENE DENOVO, and the QIMIE bioinformatic pipeline1 and principal coordinate analysis (PCoA) were used to calculate the α-diversity and β-diversity, respectively. The relative abundances of different bacterial communities at the phylum and genus levels were analyzed. The sequencing data were deposited in the Sequence Read Archive (SRA) under the accession number PRJNA735102.

Statistical Analysis

Statistical analysis was performed using SPSS 20.0 software, and the threshold for statistical significance was $P < 0.05$. All microbial count data were log$_{10}$-transformed, and all figures were constructed using Adobe Illustrator CS 6.0.

RESULTS

Fermentation Properties of Stylo and Rice Straw Silage During Ensiling

Tables 1, 2 show the fermentation parameter dynamics of the stylo and rice straw silage. The lactic acid, acetic acid, and propionic acid contents increased, and the weight loss; pH; numbers of coliform bacteria, yeast, and mold and ammonia-N content decreased during ensiling (all $P < 0.05$).

Bacterial Community Dynamics During Ensiling

In the stylo silage treatments, PCoA1 and PCoA2 accounted for 28.6% and 50.7% of the total variance; in the rice straw silage treatments, PCoA1 and PCoA2 accounted for 13.8% and 16.3% of the total variance, respectively (Figure 1). Figure 2 shows the relative bacterial community abundances at the phylum and genus levels. Proteobacteria and Firmicutes were the dominant phyla in both the rice straw and stylo silage, and their relative abundances decreased during ensiling. The abundance of Lactobacillus in the silage after pyroligneous acid treatment was higher than that in the control silage (Figures 2, 3). Adding 1% pyroligneous acid increased the relative abundances of Leuconostoc on days 3 and 7 in the stylo silage, and adding 2% pyroligneous acid increased the relative abundances of Leuconostoc and Lactococcus in the rice straw silage on days 7 and 14, respectively (Figures 2, 3). In the stylo silage, the relative abundance of Novosphingobium spp. increased, and the relative abundances of Enterobacter and Kosakonia decreased after pyroligneous acid treatment (Figures 2, 3). Serine, arginine, nitrogen, glycine, proline, and threonine metabolism decreased after adding pyroligneous acid (Figure 4). Thus, adding pyroligneous acid may reduce potential pathogens on forage surfaces during ensiling (Figure 5). Adding pyroligneous acid also enhanced fermentation and reduced hydrocarbon degradation.

Gas and CO$_2$ Production During Ensiling

Gas was produced in accordance with CO$_2$ production and was drastically increased in both silages during week 1 (Figure 6). CO$_2$ production reached its maximum on day 14 (178 mL) in the naturally fermented stylo and on day 7 (317 mL) in the rice straw silage without additives owing to the different plant species and microorganisms in the two materials. Adding pyroligneous acid decreased the gas and CO$_2$ production in both silages. Adding pyroligneous acid to the laboratory silos reduced the CO$_2$ content of 100 g of stylo silage by 66 mL and of 100 g of rice straw silage by 84 mL.

The gas and CO$_2$ production increased substantially in the early stages of ensiling. Pyroligneous acid treatment increased the relative abundances of Leuconostoc spp. and decreased the pH and relative abundances of Lactococcus spp. After 14 days of ensiling without adding pyroligneous acid, the relative abundances of Lactococcus spp. decreased in the stylo silage. Adding 1% pyroligneous acid to the silage on days 14 and 30 increased and enhanced the relative abundances of Clostridium spp. (Figures 2, 3). Lachnoclostridium was active on day 7 but was weakened during ensiling. The relative abundance of Lachnoclostridium also decreased after pyroligneous acid treatment. The relative abundance of Prevotella in the rice straw silage was higher on days 7 and 14 than on days 3 and 30 (Figure 3). Pyroligneous acid treatment decreased the relative abundances of Selenomonas, Enterobacter, Prevotella, and Citrobacter. Adding pyroligneous acid to the stylo silage increased the relative abundance of Methyllobacterium.

DISCUSSION

Fermentation Properties of Stylo and Rice Straw Silage During Ensiling

Silage, a traditional method of preserving fresh forage, is very common and is used in ruminant production worldwide (Araújo et al., 2020). During ensiling, epiphytic microorganisms (mostly LAB) start fermentation under anaerobic conditions and produce lactic acid, causing the pH to decrease, inhibiting harmful microorganisms, and ultimately preserving the moist forage (Weinberg and Muck, 1996). Forages such as stylo and rice straw are difficult to directly ensile owing to their low water-soluble carbohydrate content and high abundance of undesirable microorganisms (Wang C. et al., 2019; He et al., 2020). Without pyroligneous acid, the fermentation quality of the stylo and rice straw silage was low because of the relatively high pH.

DM, dry matter; FM, fresh matter; TN, total N; SEM, standard error of means; ND, not detected; T, time of ensiling; A, additives; TxA, interaction of ensiling time and additives. Means with different letters in the same column (a–d) or row (A–D) indicate a significant difference (P < 0.05).

Organic acids, especially acetic acid, are the main components of pyrolygenic acid (Zhang Y. et al., 2020), which may partly explain the lower pH (P < 0.05) and higher acetic acid content (P < 0.05) in the present study in the pyrolygenic acid-treated silages compared with those in the control silage. Plant cell respiration and microorganismal activities lead to nutrient losses during ensiling, especially in the early stages, and pyrolygenic acid can decrease these losses possibly by direct acidification, which inhibits plant cell respiration and microbial activities. Acetic acid can be used to improve the aerobic stability of silage.

Therefore, the addition of pyroligneous acid might be helpful to improves the aerobic stability of silage and further study is needed.

Wang Y. et al. (2019) reported that lactic acid produced by LAB fermentation decreased the pH in the early stage of ensiling. In the current study, the lactic acid content increased...
in pyroligneous acid-treated silage. Butyric acid is an undesirable product in silage owing to the nutrient loss resulting from secondary fermentation caused by clostridial activity (McDonald et al., 1991). Pyroligneous acid treatment significantly decreased the butyric acid content ($P < 0.05$), possibly by inhibiting the activities of *Clostridium* spp. owing to the reduced pH after adding pyroligneous acid. Protein degradation results in non-protein-N and ammonia-N accumulation in silage, which have low utilization efficiency in ruminants, thus declining the silage quality (He et al., 2019).

Animal excretion negatively impacts the economy and ecology. Therefore, effective measures should be taken to reduce or prevent proteolysis in silage. The ammonia-N content is an important index of protein decomposition during ensiling (Pahlow et al., 2003) and is influenced by coliform bacterial activity. In this study, adding pyroligneous acid decreased the ammonia-N content ($P < 0.01$), which was consistent with the decreased coliform bacterial numbers. The mold numbers in the rice straw silage also decreased with pyroligneous acid treatment, similar to that reported by Jung (2007) and Suresh et al. (2019), who found that pyroligneous acid exerted growth-inhibiting effects on fungi such as *Aspergillus* spp.

**Bacterial Community Dynamics During Ensiling**

In this study, the improved fermentation quality was in accordance with the changes in the bacterial community during ensiling. The unweighted PCoA findings reflected the distinctions in the bacterial communities among treatments. Silages ensiled without additives were separated from the additive-treated silages, suggesting that pyroligneous acid affected the bacterial communities in the silage. *Lactobacillus* is the major LAB in silage and can grow rapidly and produce...
lactic acid using water-soluble carbohydrates as substrates. *Lactobacillus* can also decrease the pH after oxygen is exhausted by plant cells and aerobic microorganisms in the early stage of ensiling. *Leuconostoc* and *Lactococcus* are main lactate-producing bacteria during ensiling and are usually used for fermentation in the early stage to effectively improve fermentation quality (Pahlow et al., 2003; Ni et al., 2018). *Novosphingobium*, a Gram-negative chemo-organotrophic bacterium, degrades various aromatic hydrocarbons. The increase in *Novosphingobium* spp. in the present study in the pyroligneous acid-treated stylo silage might have been due to the high aromatic hydrocarbon content in the pyroligneous acid (Zheng et al., 2020).

*Enterobacter* competes with LAB for oxygen and fermentation substrates and is an undesirable microorganism during ensiling; *Enterobacter* slows the decrease in the pH and increases protein degradation (Wang Y. et al., 2019). *Kosakonia* has characteristics similar to those of *Enterobacter* (Li et al., 2016), and its abundance in stylo silage was also reduced by...
FIGURE 5 | Heatmap of phenotypic characteristics and predicted functional profiles of detected bacterial communities in stylo and rice straw before and after ensiling for 3, 7, 14, and 30 days with or without 1% or 2% pyroligneous acid.

pyroligneous acid treatment, possibly owing to the rapid decline in the pH that was inhibiting its growth. Notably, undesirable microorganisms such as *Enterobacter* can produce ammonia-N by fermenting amino acids. Dunière et al. (2013) reported that some amino acid decarboxylation may lead to accumulation of biogenic amines, which negatively affects animal health. Ensiling and adding pyroligneous acid improve fermentation quality owing to compounds such as organic acids, carbonyls, and phenolic derivatives—as well as the strong antimicrobial and antiviral activities of pyroligneous acid (Li et al., 2018; Suresh et al., 2019). Pyroligneous acid is reported to inhibit undesirable microorganisms, including *Escherichia*, *Enterobacter*, *Pseudomonas*, and *Listeria*, similar to the findings of the present study. Antibiotics are responsible for the present spread of multi-antibiotic-resistant bacteria, and many countries such as China ban the use of antibiotics in animal feed. Thus, as a natural antibacterial agent, pyroligneous acid may be a good alternative to conventional drugs in livestock farming.

Gas and CO$_2$ Production During Ensiling

In the early stage of silage fermentation, CO$_2$ and other gases are produced via respiration by plant cells and microorganisms, leading to gas accumulation. However, the gases produced from ensiling have attracted little attention although they may cause nutrient losses and the add to the greenhouse effect. Gas and CO$_2$ production drastically increased in both silages in week 1, which is similar to the findings of McEniry et al. (2011). *Lactobacillus casei* and *L. plantarum* in sorghum silage can reduce gas production; thus, rapid acidification during ensiling may decrease plant cell respiration and bacterial community changes (Cai et al., 1997). Gas production by both silages increased or decreased slowly after 7 days, possibly due to the environmental hypoxia and acidification inhibiting plant cell respiration and gas-producing bacteria. Silages are fermented for approximately, 30 days before being opened and fed to ruminants. In this study, adding pyroligneous acid reduced the CO$_2$ content and thus might be an effective method of reducing greenhouse gas emissions and mitigating climate change.

Gas and carbon dioxide production increased in the early stage of ensiling, which might be correlated with the relatively high abundances of *Leuconostoc* (3.41% and 27.2% in the stylo and rice straw silage on day 3, respectively). Adding pyroligneous acid increased the relative abundances of *Leuconostoc* spp., which was inconsistent with the reduction in CO$_2$ production in the pyroligneous acid-treated silages. In the present study, the pH and relative abundances of *Lactococcus* spp. decreased with pyroligneous acid treatment, possibly owing to the decreased CO$_2$ production in the pyroligneous acid-treated silages. Bacterial community alterations may explain the changes and reduction in CO$_2$ production during fermentation after adding pyroligneous acid. Zhai and Pérez-Díaz (2020) reported that *Leuconostocaceae* are the most important microorganisms that produce CO$_2$ during anaerobic fermentation. The relative abundances of *Leuconostoc* spp. increased, and CO$_2$ production decreased in pyroligneous acid-treated silages possibly because CO$_2$ production during fermentation is a complex process, and many other bacteria are involved. One study reported that increasing the initial pH from 6.0 to 6.8 significantly increased the CO$_2$ production rate of *Lactococcus* spp. (Andersen et al., 2005).

*Clostridium* spp. are considered a major CO$_2$ source in silage (Pahlow et al., 2003). The relative abundances of *Clostridium* spp. increased, possibly because some *Clostridium* spp. are
autotrophic acetogenic bacteria that can produce important chemicals and fuels by using CO₂ (Zhang L. et al., 2020). *Lachnoclostridium*, a newly defined genus under the highly polyphyletic class *Clostridia*, showed a decreased relative abundance after pyroligneous acid treatment, consistent with that in CO₂ production. Furthermore, *Selenomonas, Enterobacter, Prevotella*, and *Citrobacter* may also be sources of CO₂ production during ensiling. Chen and Wolin (1977) presumed that *Selenomonas* spp. could ferment carbohydrates mainly to organic acids and CO₂; Converti and Perego (2002) reported that CO₂ is a major product of *Enterobacter aerogenes*; Emerson and Weimer (2017) reported that some *Prevotella* strains could produce CO₂ as the main product, and Lee et al. (2018) found that *Citrobacter amalonaticus* could produce CO₂ and H₂. In recent years, various approaches have been developed to reduce CO₂ emissions, among which, exploration of bacterial strains with CO₂ sequestration capacity might be effective. von Borzyskowski et al. (2018) reported that *Methylobacterium* could generate biomass from CO₂ using a heterologous Calvin-Benson-Bassham cycle. Okyay and Rodrigues (2015) considered that *Brevundimonas, Sphingobacterium, Pseudomonas*, and *Acinetobacter* strains can sequester CO₂. Furthermore, the abundance of *Stenotrophomonas*, which can fix CO₂, has been reported to increase in pyroligneous acid-treated silages (Okyay et al., 2016). Wang et al. (2020) added biochar and slag to paddy fields and observed a higher relative abundance of *Sphingomonas* and lower CO₂ emissions than those of the control fields and speculated that that *Sphingomonas* could reduce CO₂ emissions and sequester soil C. The increases in the relative abundances of *Methylobacterium, Brevundimonas, Sphingobacterium, Pseudomonas, Stenotrophomonas*, and *Acinetobacter* in pyroligneous acid-treated silage might also explain the reduced CO₂ production. Therefore, increasing the abundances of microorganisms that can sequester CO₂ might be possible to isolate such microorganisms from silage. Notably, CO₂ is used in many food products because high levels can inhibit the growth of some microorganisms. For example, CO₂ treatment was reported to reduce the abundances of detrimental bacteria, such as *Pseudomonas* and *Serratia*, in milk (Lo et al., 2016). Similarly, in this study, higher abundances of *Pseudomonas* were observed in silage without pyroligneous acid treatment. Thus, adding pyroligneous acid may reduce CO₂
production by changing the bacterial communities in rice straw and stylo silage.

CONCLUSION

Pyroligneous acid improved the fermentation quality of rice straw and stylo silage by increasing the lactic acid content and decreasing the weight losses, ammonia-N content, pH, butyric acid content, and coliform bacterial numbers. Additionally, pyroligneous acid increased the relative abundance of Lactobacillus and decreased that of undesirable bacteria such as Enterobacter and Lachnocastridium. CO₂ production was reduced during ensiling, and pyroligneous acid treatment increased the relative abundances of CO₂-fixing genera. Given the immense production and demand for silage worldwide, application of pyroligneous acid may be an effective means of alleviating climate change caused by CO₂ emissions.
