We explore the effect of the third nearest-neighbors on the magnetic properties of the Heisenberg model on an anisotropic triangular lattice. We obtain the phase diagram of the model using Schwinger-boson mean-field theory. Competition between Néel, spiral and collinear magnetically ordered phases is found as we vary the on the ratios of the nearest, J₁, next-nearest, J₂, and third-nearest, J₃, neighbor exchange couplings. A spin liquid phase is stabilized between the spiral and collinear ordered states when J₂/J₁ \geq 1.8 for rather small J₃/J₁ \lesssim 0.1. The lowest energy two-spinon dispersions relevant to neutron scattering experiments are analyzed and compared to semiclassical magnon dispersions finding significant differences in the spiral and collinear phases between the two approaches. The results are discussed in the context of the anisotropic triangular materials: Cs₂CuCl₄ and Cs₂CuBr₄ and layered organic materials, \kappa-(BEDT-TTF)₂X and Y[Pd(dmit)₂]₂.

I. INTRODUCTION

Quantum spin liquids (QSL) are exotic states of matter with no broken symmetries even at zero temperature. Fractional excitations such as deconfined spin S = 1/2 spinons are expected to occur as well as emergent gauge fields. These exotic phenomena are typically explored in low-dimensional S = 1/2 systems. However, understanding the precise conditions for the realization of a QSL is a major challenge in theoretical condensed matter physics. For instance, in the one-dimensional S = 1/2 Heisenberg model, low energy magnetic excitations are not the conventional S = 1 magnons expected in an ordered magnet but S = 1/2 spinons which propagate as domain walls along the chain. While this is a well understood example of fractionalization, the existence of such fractional excitations in a two-dimensional spin system remains unsettled.

As well as the fundamental theoretical interest further impetus to investigate QSLs has arisen from recent experimental observations identifying several materials in which such unconventional behavior may be realized. The \kappa-(BEDT-TTF)₂X and Y[Pd(dmit)₂]₂ families of organic charge transfer salts include spin liquid materials such as \kappa-(BEDT-TTF)₂Cu₂(CN)₃ and Me₂EtSb[Pd(dmit)₂]₂ where Et = C₈H₈ and Me = CH₃ in contrast to other antiferromagnetically ordered Mott insulators such as the X =Cu[N(CN)₂]Cl salts. There have also been predictions of a spin liquid in MoS₃[Sr(TMTSF)]₂, where the molecules themselves provide a triangular motif. There are also a number of possible spin liquids in inorganic materials. Cs₂CuCl₄, does not display spiral magnetic order down to T = 0.62 K and Cs₂CuBr₄ is also a candidate system for spin liquid behavior. Both the organic and inorganic materials discussed above have been primarily modeled in terms of the Heisenberg model on an anisotropic triangular lattice with exchange constants J₁ and J₂. The organic materials \kappa-(BEDT-TTF)₂Cu₂(CN)₃ and Me₂EtSb[Pd(dmit)₂]₂ are in the regime J₂/J₁ \approx 0.7, whereas Cs₂CuCl₄ (J₂/J₁ \approx 3) and Cs₂CuBr₄ (J₂/J₁ \approx 2) are closer to the weakly coupled chain limit. Other materials which may display spin liquid behavior are Ba₃CoSb₂O₉ (Ref. 7) and Ba₃CuSb₂O₉ (Ref. 8) which have isotropic triangular lattices J₂/J₁ = 1.

There are several experimental observations which suggest the existence of spin liquid behavior in these materials. Susceptibility and NMR measurements in \kappa-(BEDT-TTF)₂Cu₂(CN)₃ and Ba₃CuSb₂O₉ find no magnetic order down to very low temperatures much lower than J₁. The specific heat probing magnetic excitations reveals a linear temperature dependence in such Mott insulators suggesting the existence of a Fermi surface consisting of fractional excitations (spinons) in such Mott insulators. In \kappa-(BEDT-TTF)₂Cu₂(CN)₃, a power-law T-dependence, 1/T \propto T^{3/2} below 1 K is observed. The absence of magnetic order together with the power-law T-dependence suggest the vanishing of the gap to triplet excitations. NMR experiments on Cs₂CuCl₄ show a linear dependence of the relaxation rate with temperature 1/T \propto T in the short range ordered region T > 0.62 K. In the same temperature range neutron scattering experiments observe a continuum of excitations constant with the presence of deconfined spinons.

The above unconventional behavior is difficult to understand theoretically. For instance, there is overwhelming numerical evidence that the Heisenberg model on an isotropic triangular lattice has the 120° Néel ordered state as the ground state in contrast to Anderson’s original prediction for a spin liquid. This
seems consistent with the antiferromagnetic (AF) order observed in the nearly isotropic organic materials: Me₆Sb[Pd(dmit)₂]₂ and Me₂Et₂As[Pd(dmit)₂]₂. However, it is inconsistent with observations in isotropic triangular lattice materials: Ba₃CoSb₂O₉ and Ba₃CuSb₂O₉. Hence, other interaction terms not present in the nearest-neighbor Heisenberg model should be included to explain discrepancies with the observations.

One possible route to spin liquid behavior is the presence of further neighbor AF exchange couplings not considered in the nearest-neighbor models. These can be generated through the, second order, superexchange mechanism, i.e., $J_3 \propto t_2^3/U$, where $t_3$ is the hopping integral between third neighbouring sites, between the third-nearest neighbor sites. Alternatively fourth order process can give rise a $J_4 \propto t_1^2 t_2^2/U^3$, where $t_1$ and $t_2$ are the nearest and next nearest neighbour hopping integrals. These fourth order process also give rise to a ring exchange term, $J_3(S_i \cdot S_j)(S_k \cdot S_l)$, where $S_i$ is the Heisenberg spin operator on the $i^{th}$ site.

Second and third nearest neighbor AF exchange coupling frustrates magnetically ordered phases and can lead to spin liquid behavior. For instance, Wang and Vishwanath have found spin disordered flux phases in the large quantum fluctuation regime when $S < 1/2$. Ring exchange can also lead to spin liquid behavior on the isotropic triangular and anisotropic triangular lattices. On the isotropic triangular lattice the two contributions generated by four order processes lead to spin liquid behavior $(J_3/J_1 > 0.1)$ which is characterized by gapless magnetic excitations and a spinon Fermi surface. It is then interesting to understand the effect of each contribution separately. Alternatively, other mechanisms may also stabilize spin liquids. For example, it has been argued that the Dzyaloshinskii-Moriya interaction may also produce a spin liquid behavior in Kagomé lattices and anisotropic triangular lattices.

The main aim of the present work is to analyze the effect of next-nearest neighbor interaction, $J_3$, on the magnetic properties of the Heisenberg model on anisotropic triangular lattices. Since these interactions can be generated by fourth order process that also lead to ring exchange as discussed above, our work contributes to the general understanding of ring exchange effects on frustrated antiferromagnets. We use Schwinger boson mean-field theory (SB-MF) expressed in terms of antiferromagnetic and ferromagnetic bonds which are treated as variational parameters. The Schwinger boson approach is particularly useful since it can describe ordered and disordered phases on equal footing: the magnetically ordered phases resulting from the condensation of the bosons at particular order wavevectors of the system. We find that when the anisotropy $J_3/J_1 \gtrsim 1.8$ of the system is amenable to spin liquid behavior under the effect of a weak next-nearest neighbor interaction, $J_3/J_1 \lesssim 0.1$. Since these results are obtained from Schwinger boson mean-field theory which favors broken symmetry magnetic phases, our results suggest that the spin liquid phase found here is robust against fluctuations. This spin liquid discussed below is most relevant to the spin liquid candidate materials typically modelled through anisotropic triangular lattices with $J_2/J_1 > 1$ such as Cs₂CuCl₄ and Cs₂CuBr₄ for which the third nearest-neighbor interactions are typically neglected.

The present paper is organized as follows: in section the $J_1 - J_2 - J_3$ Heisenberg model studied is introduced. In section the Schwinger boson formulation is briefly revised and main issues described. In section the ground state energies, magnetization and phase diagram obtained with SB-MF are obtained and discussed. Elementary magnetic excitations of the system are discussed in Section. We finally end up with conclusions and the relevance to anisotropic triangular lattice materials in section.

II. HEISENBERG MODEL ON AN ANISOTROPIC TRIANGULAR LATTICE WITH THIRD-NEXT-NEIGHBOR INTERACTIONS

We are interested in understanding the magnetic properties of the Heisenberg model on the anisotropic triangular lattice including exchanges up to third nearest-neighbor spins:

$$H = J_1 \sum_{\langle ij \rangle} S_i \cdot S_j + J_2 \sum_{\langle\langle ij \rangle\rangle} S_i \cdot S_j + J_3 \sum_{\langle\langle\langle ij \rangle\rangle\rangle} S_i \cdot S_j.$$  (1)

We take from now on $J_1 = 1$ unless otherwise stated. Sum $\langle ij \rangle$ runs over nearest-neighbors, $\langle\langle ij \rangle\rangle$ runs over next nearest-neighbors and $\langle\langle\langle ij \rangle\rangle\rangle$ over third nearest-neighbor pairs of sites. The anisotropic triangular lattice model with no third-nearest neighbors, $J_3 = 0$,
has been studied extensively. Related models including ring exchange contributions also have been recently analyzed. For the particular case of the isotropic triangular case, \( J_2 = 1 \) and \( J_3 = 0 \), Sachdev finds a spin liquid phase which becomes the long range 120° magnetically ordered state when the quantum fluctuations are reduced to \( S = 1/2 \) within a \( \text{Sp}(N) \) formulation of the Heisenberg model where \( N \) is the number of spin species. The general \( J_2 \neq 1 \) situation has been explored using exact diagonalization and DMRG techniques linear spin-wave theory (LSWT), modified spin-wave theory, series expansions, mean-field Schwinger boson theory and large-\( N \) approaches. In the region where a transition from Néel antiferromagnetism to spiral order occurs \( (J_2 = 0.5 \) within LSWT) a spin liquid has been speculated to exist. The isotropic triangular lattice model, \( J_2 = 1 \), under the effect of \( J_3 \) has been studied using Schwinger boson mean-field theory and recently revisited. Spin liquid phases have recently been found in the Hubbard model on the anisotropic triangular lattice.

**Classical limit:** the classical ground state energy of model (1) is evaluated considering planar helices only. The spin at each site is given by: \( S_i = S \cos(Q \cdot R_i)e_1 + S \sin(Q \cdot R_i)e_2 \), \( e_1 \) and \( e_2 \) being an orthonormal basis and \( Q = (Q_x, Q_y) \) the ordering wavevector. The classical phase diagram is obtained by comparing the energies of the spiral \( (Q = (Q, Q)), \) collinear \( (Q = (0, \pi)) \) and Néel \( (Q = (\pi, \pi)) \) orders. The wave vector of the spiral phase is given by:

\[
Q = \arccos \left( -J_2 + \sqrt{J_2^2 + 12J_3(3J_3 - 1)} \right). \tag{2}
\]

The phase diagram resulting from these three phases is shown in Fig. 2. For \( J_3 \to 0 \) the transition between Néel and spiral order with \( Q = \arccos(-1/2J_2) \) occurs at \( J_2 = 0.5 \) as expected for the anisotropic triangular lattice. In the isotropic limit, \( J_2 = 1 \), the transition from the spiral to collinear or Néel orders occurs at \( J_3 = 1/8 \). This is in agreement with the spin wave analysis of model (1) on the isotropic triangular lattice: \( J_1 = 1, J_2 = 1 \) and \( J_3 = 0/2 \).

**III. SCHWINGER BOSON MEAN-FIELD THEORY**

The quantum magnetism of bipartite (unfrustrated) lattices can be explored using the Schwinger bosonic representation of \( SU(N) \) Heisenberg models. Extensions to frustrated lattices can be done by using the \( \text{Sp}(N) \) representation. Here, we use the \( \text{SU}(2) \) mean-field theory introduced by Cecatto et al. which keeps ferromagnetic and antiferromagnetic components in the mean-field approach. Such mean-field decoupling was found to correspond to the large-\( N \) limit of a "symplectic-\( N \)" representation of the spins, which appropriately takes into account time-reversal properties of the spins in frustrated magnets. The Schwinger boson approach can describe both magnetically ordered and disordered states complementing other semiclassical spin-wave theories. We now summarize the main steps in the Schwinger mean-field approach to the Heisenberg model (1) following previous works.

Schwinger bosons are used to express the Heisenberg interaction terms in the model (1). Each bond between two different sites is expressed through the operator identity:

\[
S_i \cdot S_j = : \hat{B}_{ij}^\dagger \hat{B}_{ij} : - \hat{A}_{ij}^\dagger \hat{A}_{ij}, \tag{3}
\]

where \( : \) is normal ordering, and the operators \( \hat{A}_{ij} \) and \( \hat{B}_{ij} \) are defined in terms of the Schwinger bosons as:

\[
\hat{A}_{ij} = \frac{1}{2} (a_{ij}^\dagger a_{ij} + a_{ij} a_{ij}^\dagger), \quad \hat{B}_{ij} = \frac{1}{2} (a_{ij}^\dagger a_{i\uparrow}^\dagger + a_{ij} a_{ij}), \tag{4}
\]

where \( a_{ij}^\dagger \) and \( a_{ij} \) create a "spin up" and "spin down" Schwinger boson on site \( i \). The two operators, \( \hat{A}_{ij} \) and \( \hat{B}_{ij} \), describe antiferromagnetic and ferromagnetic bonds between \( i \) and \( j \) sites, respectively.

The magnitude of the spin is fixed by restricting the number of bosons per site:

\[
\sum_\sigma a_{i\sigma}^\dagger a_{i\sigma} = 2S, \tag{5}
\]

which is the constraint equation imposed over the Schwinger bosons avoiding having an arbitrary number of bosons at each site.

After a mean-field decoupling of the quartic terms describing the bonds, the Heisenberg model (1) can be ex-
After Fourier transformation, the mean-field Hamiltonian reads:

\[
H = J_1 \sum_{\langle ij \rangle} (B_{ij}^* \hat{B}_{ij} - A_{ij}^* \hat{A}_{ij} + H.c.)
+ J_2 \sum_{\langle\langle ij \rangle\rangle} (B_{ij}^* \hat{B}_{ij} - A_{ij}^* \hat{A}_{ij} + H.c.)
+ J_3 \sum_{\langle\langle\langle ij \rangle\rangle\rangle} (B_{ij}^* \hat{B}_{ij} - A_{ij}^* \hat{A}_{ij} + H.c.)
+ J_1 \sum_{\langle ij \rangle} (-B_{ij}^* B_{ij} + A_{ij}^* A_{ij})
+ J_2 \sum_{\langle\langle ij \rangle\rangle} (-B_{ij}^* B_{ij} + A_{ij}^* A_{ij})
+ J_3 \sum_{\langle\langle\langle ij \rangle\rangle\rangle} (-B_{ij}^* B_{ij} + A_{ij}^* A_{ij})
+ \lambda \sum_{i} \left( \sum_{\sigma} (a_{i,\sigma}^\dagger a_{i,\sigma}) - 2S \right).
\]  \tag{6}

The variational energy of the system is minimized with respect to \(A_{ij}\) and \(B_{ij}\) and the Lagrange multiplier \(\lambda\) fixes the constraint \(\langle A_{ij} \rangle\) at each site on average. The resulting set of self-consistent equations obtained are:

\[
\langle A_{ij} \rangle = A_{ij},
\langle \hat{B}_{ij} \rangle = B_{ij},
\sum_{\sigma} \langle a_{i,\sigma}^\dagger a_{i,\sigma} \rangle = 2S,
\]  \tag{7}

and the variational bond energy reads:

\[
\langle S_i \cdot S_j \rangle = |B_{ij}|^2 - |A_{ij}|^2.
\]  \tag{8}

After Fourier transformation, the mean-field Hamiltonian reads:

\[
H^{MF} = \sum_{k,\sigma} (B(k) + \lambda) a_{k,\sigma}^\dagger a_{k,\sigma}
- i \sum_k A(k) (a_{k\uparrow} a_{-k\downarrow} + a_{k\downarrow} a_{-k\uparrow}) - 2\lambda N_s S,
\]  \tag{9}

with \(N_s\) the number of sites in the lattice. The coefficients \(A(k)\) and \(B(k)\) are given by:

\[
A(k) = \frac{1}{2} \sum_{\delta_i} J_i \sin(k \cdot \delta_i) A_{\delta_i},
B(k) = \frac{1}{2} \sum_{\delta_i} J_i \cos(k \cdot \delta_i) B_{\delta_i},
\]  \tag{10}

where the sums are performed over the \(\delta_i\) vectors connecting pairs of sites coupled by \(J_i\); \(\delta_i\) refers to the vector connecting nearest neighbor, \(\delta_2\) next-nearest neighbor and \(\delta_3\) third nearest-neighbor sites. The variational parameters satisfy: \(A_{-\delta_i} = -A_{\delta_i}\) and \(B_{-\delta_i} = B_{\delta_i}\), when evaluating the sums over \(\delta_i\).

A Bogoliubov transformation is performed to diagonalize the Hamiltonian. This leads to the following mean-field Hamiltonian:

\[
H^{MF} = \sum_{k,\sigma} \omega(k) (\alpha_{k,\sigma}^\dagger \alpha_{k,\sigma} + \frac{1}{2}) - N_s \lambda (1 + 2S).
\]  \tag{11}

where the Bogoliubov quasiparticle operator is expressed as:

\[
\alpha_{k,\sigma}^\dagger = \cosh(\theta_k) a_{k,\sigma}^\dagger - \sinh(\theta_k) a_{-k,\sigma},
\]

in terms of the original bosons with:

\[
\tanh(\theta_k) = -\frac{A(k)}{B(k) + \lambda}.
\]

These Bogoliubov quasiparticles have the following dispersion:

\[
\omega(k) = \sqrt{(B(k) + \lambda)^2 + A(k)^2}.
\]  \tag{12}

From the minimization of the total energy, \(E_0 = \langle H^{MF}\rangle\), a set of self-consistent equations:

\[
\frac{1}{2N_s} \sum_k A(k) \sin(k \cdot \delta_i) = A_{\delta_i},
\]

\[
\frac{1}{2N_s} \sum_k B(k) + \lambda \cos(k \cdot \delta_i) = B_{\delta_i},
\]

\[
\frac{1}{2N_s} \sum_k B(k) + \lambda \omega(k) = \frac{1}{2} + S,
\]  \tag{13}

are obtained at temperature \(T = 0\), which are numerically solved.

In a finite lattice with \(N_s\) sites magnetic ordering with a particular order is signalled by a minimum gap in the spinon dispersion (located at \(\pm Q/2\)) which scales as:

\(\omega_{\pm Q/2} \sim 1/N_s\), scaling to zero with the system size. In the thermodynamic limit, these modes go to zero and Bose condensation occurs at these wave vectors which signals a magnetically ordered state with ordering vector, \(Q\). In infinite lattices, the sums in Eq. \((13)\) are converted into integrals separating the macroscopic contribution of the condensed boson fraction at \(\pm Q/2\), which is treated as a self-consistent parameter, \(m(Q)\). The self-consistent equations \((13)\) are solved under the extra condition: \(\omega_{Q/2} = 0\), which fixes \(\lambda = A(Q/2) - B(Q/2)\) at each iteration.

In large but finite systems, the magnetization can be obtained from:

\[
m(Q) = \frac{1}{N_s} \frac{B(Q/2) + \lambda}{\omega(Q/2)}.
\]  \tag{14}

We have checked that the magnetization, \(m(Q)\), and total energy, \(E_0\), converge to the thermodynamic limit results as the number of sites, \(N_s\), is increased. One can show that the classical ground state energy is recovered by SB-MFA in the \(S \rightarrow \infty\) limit as it should (see Appendix for details).

\section{Ground State Properties}

We now analyze the ground state properties of the Heisenberg model \((1)\). We first discuss the phase diagram of the anisotropic triangular lattice and then the
effect of the third nearest-neighbor interactions, $J_3$, on the phase diagram.

A. Anisotropic triangular lattice model ($J_3 = 0$)

It is illustrative to analyze first the ground state properties of the anisotropic triangular lattice ($J_3 = 0$) with the SB-MF approach. In Fig. 3 we plot the $J_2$ dependence of magnetization and total energy. The magnetic wave vector, $Q$, changes continuously from $(\pi, \pi)$ to $(Q, Q)$ at $J_2 \approx 0.62$, which is larger than the classical transition point: $J_2 = 0.5$ with no disordered phase found between Néel and spiral phases. Although the shift to higher $J_2$ critical values than the classical ones is consistent with series expansion results, the SB-MF fails to describe the disordered region around $0.7 < J_2 < 0.9$ or the disordered phase at $J_2 = 0.5$ predicted by linear spin-wave theory (LSWT). On the other hand, increasing $J_2 \approx 2.2$ a transition to a disordered state occurs consistent with the expected spin liquid phase in decoupled $S = 1/2$ spin chains ($J_1 = 0$). Note that this critical SB-MF value is much smaller than $J_2 \approx 3.8$ from LSWT or series expansions, $J_2 \approx 4.5$.

B. Effect of third nearest-neighbor interactions ($J_3 \neq 0$)

We now analyze the effect of the third nearest-neighbor interaction. Results for the total energy per site and magnetization dependence on $J_3$ are shown in Fig. 4 for different $J_2$.

The isotropic triangular lattice case has been previously studied with Schwinger bosons and recently revisited. A first-order transition from $120^\circ$-Néel ordering ($Q = (2\pi/3, 2\pi/3)$) to collinear order with $Q = (0, \pi)$ occurs at about $J_2 \approx 0.16$. These values should be compared with the classical spin wave values with the spiral-collinear transition occurring at: $J_2 = 1/8$. The direct spiral-collinear transition survives up to: $J_2 \gtrsim 1.8$, at which a disordered spin liquid is stabilized between the $(Q, Q)$-spiral and $(0, \pi)$-collinear order.

The dependence of the ordering wave vector, $Q$, with $J_3$ is shown in Fig. 5 for different $J_2$. The absolute value of $Q$ in $Q = (Q, Q)$ is plotted as a function of $J_3$ until the jump to the $(0, \pi)$ phase occurs showing the discontinuous behavior of the order parameter signalling the first order transition. For comparison, we plot the dependence of the classical ordering wavevector as a function of $J_3$ showing how the transition point ($J_3^*$) is shifted to larger values by the quantum fluctuation effects. Also it shows how the SB-MF ordering vector is enhanced with respect to the classical ordering vector for $J_2 < 1$ and is reduced when $J_2 > 1$ independent of the value of $J_3$. For $J_2 = 1$, the SB-MF ordering vector $Q = 2\pi/3$ is identical to the classical wave vector. Our results extend previous studies for the anisotropic triangular case with: $J_3 = 0$.

We summarize the results of ground state properties of the $J_1 - J_2 - J_3$ model of Fig. 5 in which the SB-MF phase diagram is compared with the classical phase diagram in Fig. 2.

V. MAGNETIC EXCITATIONS

We now discuss the elementary excitations of the system in different parameter regimes. Magnetically ordered states can be described with the infinite lattice version of the SB-MF with the extra condition: $\omega(\pm Q/2) = 0$. These type of solutions are recovered in large but finite lattices by using equations (13) with no extra condition. These solutions do not break the spin symmetry but have dispersions with a minimum energy which behaves as: $\omega(\pm Q/2) \propto 1/N$. Disordered phases preserving the SU(2) spin symmetry of the hamiltonian are described through the version of the SB-MF approach expressed in Eq. 13.

A. Elementary excitations: one-spinon dispersions

The elementary excitations in the spin liquid phase described through SB-MF are the $S = 1/2$ spinons. These can be visualized within Anderson "resonant valence bond" (RVB) theory as $S = 1/2$ defects propagating in the background of resonating singlets covering the rest of the lattice. The SB-MF theory presented here including singlet $A_{ij}$ and triplet $B_{ij}$ correlations corresponds to a large-$N$ saddle point, which appropriately deals with the time-reversal properties of the spin in contrast to previous $Sp(N)$ theories. At the large-$N$ saddle point or the SB-MF theory ($N = 2$) presented here, spinons are non-interacting.

The evolution of the one-spinon dispersion starting from the ordered $(Q, Q)$ spiral phase as $J_3$ is increased with $J_2 = 2$ is shown in Fig. 6. Initially when $J_3 = 0$, the spinon dispersion is gapless and the spinons are Bose condensed at the $\pm Q/2$ wave vectors leading to a small but finite magnetization. As $J_3$ is increased and the disordered spin liquid reached the spinon dispersion develops a gap at $\pm Q/2$ and long range order is lost. The evolution of the spinon dispersions starting from the collinear-(0, $\pi$) phase is also shown in Fig. 6 showing how the the gap opens at $(0, \pm \pi/2)$ on entering the spin liquid phase.

B. Two-spinon excitations

The $S = 1/2$ Heisenberg antiferromagnetic chain with nearest-neighbor interaction, $J$, has no long range magnetic order and no energy gap to the lowest excitation dispersion: $\omega_q = \frac{\pi J}{2} |\sin q|$. Hence, magnetic excitations consist of a two-spinon continuum different from the
well defined dispersion of magnons, the magnetic quasi-particles expected in a three-dimensional ordered Heisenberg antiferromagnet.

Within SB-MF, the triplet excitations can be formed by the composition of two spin-1/2 deconfined spinons. These form a broad particle-hole continuum which reaches high energies with the minimum excitation energy related to magnetic order in ordered phases. In an ordered phase the lowest magnetic excitations are obtained by creating a spinon in the condensate and another spinon in the continuum. The minimum two-spinon excitation energies read:

\[ \epsilon_k^\pm = \omega_{\mp<Q/2} + \omega_{k\pm Q/2}, \]  

where \( \omega_{\pm<Q/2} \to 0 \), and \( \epsilon_k^\pm = \omega_{k\pm Q/2} \) in an ordered phase.

In Fig. 7 we show the minimum two-spinon excitation energies of the continuum, \( \epsilon_k^\pm \), as obtained from Eq. (15) on an anisotropic triangular lattice (\( J_3 = 0 \)). This is plotted in Fig. 7 for different \( J_2 \) and compared to magnons obtained from spin-wave theory. We show the evolution of these dispersions when going from the Néel to the spiral phases including the isotropic triangular lattice case already discussed in the literature.\(^{41}\)

(i) Néel phases: In the Néel phases we find that the lowest SB-MF dispersions are very similar to the conventional magnon excitations. This is shown in Fig. 7 for \( J_2 = 0.25 \). The only important effect is the smaller width of the SB-MF dispersions as compared to the semi-classical LSWT dispersion. This is due to renormaliz-
FIG. 5: (Color online) Ordering wavevector and Schwinger boson mean-field phase diagram of the $J_1 - J_2 - J_3$ model on an anisotropic triangular lattice. In the left panel, the dependence of $Q$ on $J_3$ showing the transition from the spiral: $(Q, Q)$, to the collinear $(0, \pi)$ phase for which we set $Q = \pi$ for the purposes of this figure from SB-MF (solid lines) is compared to the classical wavevector dependence. The ground state phase diagram obtained from SB-MF (solid lines) is compared with the classical phase diagram (dashed lines) in the right panel showing the parameter range in which the spin liquid phase (QSL) is stable.

FIG. 6: (Color online) Spinon dispersion for the $J_1 - J_2 - J_3$ model with $J_2 = 2$ and various $J_3$. In a) we show the evolution of the spinon dispersion along the diagonal $(k, k)$-direction of the Brillouin zone from the magnetically ordered spiral-$(Q, Q)$ phase to the spin liquid phase. In b) the evolution of the spinon dispersion in the $(0, k)$ direction from the collinear-$(0, \pi)$ to the spin liquid is shown. The spin liquid phases are characterised by the opening of a gap.

tion effects since the SB-MF theory contains static interaction effects in a similar way as Hartree-Fock theory contains band renormalization and band shift effects in interacting electron models. Series expansion calculations in this regime have found the development of 'roton' minima around $(\pi, 0)$ in the $(\pi, 0) \to (\pi/2, \pi/2)$ direction with a lower energy at $(\pi, 0)$ with respect to the $(\pi/2, \pi/2)$ wavevector. Both LSWT and SB-MF disagree with the series expansion result which predict a flat dispersion between these wavevectors. A simple interpretation in terms of non-interacting spinons for these 'roton' minima does not seem adequate and one should possibly need to go beyond the mean-field theory and include spinon-spinon interactions.

(ii) Spiral phases: When entering the spiral phase we find the strongest deviations of the dispersions with respect to the LSWT. Already for $J_2 = 0.7$ (Fig. 7) we find that apart from the renormalization effects discussed above there are also qualitative differences in the momentum dependence in the $(\pi, 0) \to (\pi, \pi)$ direction. In the isotropic triangular case there is a flat band dispersion between $(\pi, 0) \to (\pi, \pi)$ in LSWT which is not observed
in the SB-MF dispersion but rather a minimum (maximum) occurs in the lowest (highest) branch at $(\pi, \pi)$ and dips at the $(\pi, 0)$ and $(0, \pi)$ point which compare well with the roton minima observed in the series expansion results. This minima can be associated with the existence of $(\pi, \pi)$-Néel and $(0, \pi)$-collinear correlations in the $(Q, Q)$-spiral ordered phase. For larger $J_2$ the differences with the spin wave dispersion become more pronounced particularly around $(\pi, \pi)$ where a deeper dip is observed compared to the LSWT magnon dispersions as in Fig. 7.

(iii) Spin liquid formation: We now discuss the evolution in the large $J_2$ limit where a spin liquid phase occurs. In Fig. 8 we fix $J_2 = 2$ and increase $J_3$ so that we eventually enter the spin liquid phase. For $J_3 = 0.05$ the system is already in the spin liquid phase and a small gap opens in the dispersion around the short range ordering spiral vector $(Q, Q)$. Concomitantly there is also a change in the momentum dependence of the dispersion with suppression of the dispersion at $(\pi, 0)$ as compared to the $J_3 = 0$ case which indicates the proximity to the collinear phase. This is consistent with the expected behavior as extracted from the phase diagram (see Fig. 5). We also show in Fig. 8 the spin liquid phase obtained for $J_3 = 0.1$.

The above low energy magnetic dispersions will be modified in general in the presence of finite-$N$ fluctuations around the saddle point. These generate gauge interactions that bind the spinons which in the ordered phases lead to magnons in the neighborhood of the Goldstone modes. On the other hand, at high-energy, pairs of spinons remain weakly bound.

C. Dynamical magnetic correlations

The dynamics of the spin correlations in the system can be analyzed through inelastic magnetic neutron scattering experiments which probe the $\Delta S = \pm 1$ excitations. If there are magnons present in the magnetic excitation spectra, as in conventional magnets, then sharp quasi-particle peaks are found in the neutron scattering spectra. Since spinons carry half of the local spin degree of freedom at each lattice site, $\Delta S = \pm 1$, magnetic excitations observed in neutron scattering can occur from the triplet combination of two spinons. Within SB-MF, spinons are deconfined leading to a two-spinon continuum rather than the sharp magnon quasiparticle peaks of conventional magnets. The dynamical spin correlation function obtained in the SB-MF then reads:

$$S^{zz}(k, \omega) = \sum_n |\langle O| S^z_k |n \rangle|^2 \delta(\omega - (E_n - E_0)),$$

with $S^z_k = \sum_\sigma e^{i k \cdot R} s^z_\sigma$, and $S^z_s = \frac{1}{2} (a_i^\dagger a_{i+} - a_{i+}^\dagger a_i)$. We evaluate this expression at the mean-field level using the Schwinger boson approach. The ground state is defined as the vacuum of Bogoliubov quasiparticles: $\alpha_{k\sigma}|0\rangle = 0$ where $\alpha_{k\sigma}$ creates a Bogoliubov quasiparticle for any $k$ and $\sigma$ as in Eq. (11). Excitation $n$ is produced by creating two spinons above the vacuum.

Expressing the original boson operators in terms of the Bogoliubov quasiparticles with the two-spinon excitations: $E_n - E_{GS} = \omega_{k_1} + \omega_{-(q_1 + k_1)}$, the final expression for the spin correlation function reads:

$$S^{zz}(k, \omega) = \frac{1}{4N_s} \sum_{k_1} |u_{k+k_1} v_{k_1} - u_{k_1} v_{k+k_1}|^2 \times \delta(\omega - (\omega_{-(-k_1 + k + k_1)})),$$

with the matrix elements: $u_k = \sqrt{(1 + \frac{B(k) + \lambda}{\omega_k})/2}$ and $v_k = i \text{sign}(A(k)) \sqrt{(-1 + \frac{A(k)}{\omega_k})/2}$. The above Eq. (17) gives the spectra of $S = 1$ excitations relevant to neutron scattering consisting on two spinons. The lowest energy particle-hole processes described by $S^{zz}(k, \omega)$ correspond to exciting a spinon in the condensate and another one in the continuum. For finite size lattices: $(B(Q) + \lambda)/\omega(Q/2) = N_s m(Q)$, $u_{\pm Q/2} \sim \sqrt{N_s m(Q)/2}$ and $v_{\pm Q/2} \sim i \sqrt{N_s m(Q)/2}$ and so the weight right at $\pm Q/2$ is proportional to the magnetization.

In Fig. 9 the dynamical spin correlations, $S^{zz}(k, \omega)$ are shown for $J_2 = 2$ going from the spiral ordered phase into the spin liquid phase corresponding to parameters shown in Fig. 8. The main features observed in the spectra correspond to the elementary two-spinon branches: $\epsilon^x_k$ plotted in Fig. 8. We first concentrate in $S(k, \omega)$, evaluated at the ordering wave vector: $k = (Q, Q)$. In the ordered phase for $J_3 = 0$, there is a very low energy peak (going to zero in the infinite system) which dominates the spectra and corresponds to the Goldstone mode associated with the long range spiral magnetic order. A second smaller feature occurs at the second elementary branch of Fig. 8. Apart from these two main features, there is a contribution of particle-hole excitations which extends up to high energies. Such contribution is associated with two-spinon excitation processes involving spinons in the normal fluid (not condensed) as recently pointed out in Ref. 13.

As $J_3$ is increased, there is a redistribution of spectral weight. On entering the spin liquid phase, a gap opens up in the spectra and the spectral weight of the lowest branch is suppressed while there is an enhancement of spectral weight of the highest magnetic excitation. For the wave vector $k = 0.8(\pi, \pi)$ different from $Q$, there is also a two-peak structure similar to the one discussed above associated with $\epsilon^x_k$. However, the overall spectral weight contribution is suppressed as compared to $k = (Q, Q)$ since excitations have higher energy.

VI. CONCLUSIONS

We have analyzed the effect of a third-nearest neighbor antiferromagnetic interaction, $J_3$, on the magnetic properties of the antiferromagnetic Heisenberg model on an anisotropic triangular lattice. We have shown that $J_3$ can
frustrate the long range spiral magnetic order leading to a spin liquid phase when $J_2 > 1.8$ and a small $J_3 \lesssim 0.1$. Since SB-MF is known to favor ordered states, the parameter regime in which the spin liquid phase is stable may be enlarged by fluctuations.

The antiferromagnetic coupling, $J_3$, considered here may be generated through either, second order, superexchange processes between third nearest-neighbors sites or fourth order processes, that also drive ring exchange. Ring exchange involving four sites can be separated into
two-spin \( J_3 \) Heisenberg and four-spin\(^{22,23} \) contributions. Our present analysis, focusing on the frustrating effects associated with the former Heisenberg-type exchange terms in the ring exchange, is helpful in the understanding of ring exchange effects in frustrated antiferromagnets.

Our analysis may be relevant to recent observations suggesting spin liquid behavior in certain layered materials. \( \text{Cs}_2\text{CuBr}_4 \) is an anisotropic triangular material with \( J_2 \sim 2 \) which would be predicted to be magnetically ordered. However, from our analysis a rather small \( J_3 \) would be sufficient to turn it into a spin liquid. On the other hand, \( \text{Cs}_2\text{CuCl}_4 \) with \( J_2 \sim 3 \) would be a spin liquid from our analysis even for \( J_3 = 0 \) which is in contrast with series expansion predictions. In any case, our SB-MF analysis suggests that in these two materials \( J_3 \) may play a role in determining their magnetic properties\(^{17} \). On the other hand, organic materials in which spin liquid phases have been found such as \( \kappa-(\text{BEDT-TTF})_2\text{Cu}_2(\text{CN})_3 \) and \( \text{Me}_2\text{EtSb}[\text{Pd}(\text{dmit})]_2 \), are in a different parameter regime \( J_2 \sim 0.7 \) in which SB-MF would predict an ordered state regardless of \( J_3 \) unlike the spin liquid predicted by series expansions\(^{23} \) for \( J_3 = 0 \). On the basis of this work, one would expect a finite \( J_3 \) to further stabilize the QSL. It would be interesting to find organic materials which are in the large \( J_2 \) parameter region discussed here as they would be strong candidates for the observation of spin liquid behavior.

The SB-MF prediction for the magnetically disordered state is a \( Z_2 \) spin liquid\(^{12,14} \) characterized by gapped bosonic excitations. However, the \( T \)-dependence of the NMR relaxation rate in \( \text{Cs}_2\text{CuCl}_4 \) and \( \kappa-(\text{BEDT-TTF})_2\text{Cu}_2(\text{CN})_3 \) suggests the presence of gapless excitations in the system. This fact can be more naturally explained in terms of fermionic mean-field theories with a ground state consisting of a spinon Fermi surface\(^{12} \) but is not inconsistent with a bosonic mean-field state of the type described here with spin singlet-triplet gaps which are smaller\(^{15} \) than \( J_1/10 \). Further theoretical efforts should concentrate in understanding these observations by going beyond the mean-field theory used here using numerical techniques that can treat the constraint on the number of bosons exactly.

**Appendix A: Classical energy**

Here, we analyze how in the \( S \to \infty \) limit the ground state energy obtained from SB-MF converges to the classical ground state energy\(^{26} \). Self-consistent solutions of the bond strengths of the model in the classical limit are given by:

\[
B_{ij} \approx S \cos(\mathbf{Q} \cdot \mathbf{R}_{ij}/2) \quad (A1)
\]

\[
A_{ij} \approx S \sin(\mathbf{Q} \cdot \mathbf{R}_{ij}/2)
\]

where \( \mathbf{R}_{ij} \) is the distance between two sites forming a bond. One can check that the classical energy for a given bond is indeed recovered:

\[
\langle S_i \cdot S_j \rangle = |B_{ij}|^2 - |A_{ij}|^2 \approx S^2 \cos(\mathbf{Q} \cdot \mathbf{R}_{ij}). \quad (A2)
\]

The boson chemical potential in the magnetically ordered phase is then given by:

\[
\lambda = A(Q^2/2) - B(Q^2/2) = -SJ(Q) - S^2J_{\text{ring}}(Q) = -\frac{E_{\text{class}}}{S}, \quad (A3)
\]

where we have defined:

\[
J(Q) = J_1(\cos(Q_x) + \cos(Q_y)) + J_2(2 \cos(Q_x + Q_y) + \cos(Q_x - Q_y) + \cos(2Q_x + Q_y) + \cos(Q_x + 2Q_y)), \quad (A4)
\]

and the classical energy: \( E_{\text{class}} = S^2J(Q) \). The mean-field energy referred to the chemical potential obtained
from $H^{MF}$ reads:

$$E = \langle H^{MF} \rangle + 2\lambda S = \frac{1}{N_s} \sum_k \omega_k - S^2 J(Q) \approx E_{\text{class}},$$

(A5)

when $S$ is large since the sum over $\omega_k$ in the right hand side of the equation is of $O(S)$ only. Therefore, when $S \to \infty$ the SB-MF energy converges to the classical energy.
