(Dated: March 23, 2022)

We present low-temperature heat and charge transport as well as caloric properties of a ThAsSe single crystal. An extra $-AT^{1/2}$ term in the electrical resistivity, independent of magnetic fields as high as 14 T, provides evidence for an unusual scattering of conduction electrons. Additionally, both the thermal conductivity and specific heat show a glass-type temperature dependence which signifies the presence of tunneling states. These observations apparently point to an experimental realization of a two-channel Kondo effect derived from structural two-level systems.

PACS numbers: 66.35.+a, 72.10.Fk, 72.15.Qm

Since the pioneering work by Nozières and Blandin, the search for a two-channel Kondo (2CK) effect has been the subject of considerable scientific interest. However, its experimental realization requires a strict channel symmetry that is hard to achieve in the spin Kondo problem. As a viable alternative, one considers an equivalent Kondo effect that originates from scattering centers with orbital instead of spin degrees of freedom like, e.g., the quadrupole momenta in certain heavy-fermion systems.

In this so-called orbital Kondo effect, the spin of the conduction electrons plays the role of a silent channel index. The influence of a magnetic field on the orbital Kondo resonance must be very weak and, therefore, distinct from the destruction of the spin Kondo resonance by a comparatively low magnetic field.

As originally suggested by Zawadowski et al., the interaction between structural two-level systems (TLS) and the conduction electrons may also lead to the orbital Kondo effect and hence to the 2CK problem. In the TLS Kondo model, a single tunneling center (e.g., an atom that quantum-mechanically tunnels between two minima of a double-well potential) immersed in the Fermi sea is expected to behave like a spin-$\frac{1}{2}$ impurity coupled to the conduction electrons. Since this is essentially a one-impurity Kondo problem, a considerably stronger effect on the transport properties other than on the thermodynamic ones is anticipated. On the other hand, it is still debatable whether the strong-coupling 2CK fixed point due to the TLS can be experimentally achieved or not. This is mainly because a Kondo temperature $T_K$ as small as $10^{-3}$ to $10^{-2}$ K is expected. In addition, the contribution of higher excited states may reduce $T_K$ by up to three orders of magnitude to negligibly small values. Furthermore, even if the second vibrational level of the tunneling atom is just above the potential barrier, for an intermediate heavy atom a $T_K$ value below 0.5 K is predicted. Nevertheless, various experimental observations obtained at liquid-helium temperatures are thought to be caused by an interaction between the conduction electrons and TLS. For example, an orbital Kondo problem with large $T_K$ value is inferred from the width of the Kondo resonance on the Cr(001) surface investigated by scanning tunneling microscopy. Moreover, recent theoretical studies have shown that not all of the possible internal structures of the defect have been explored. Finally, a significant enhancement of the Kondo temperature is suggested if the conduction electrons are coupled to the tunneling impurity via resonant scattering.

Recent work on the diamagnetic compound ThAsSe has demonstrated the importance of tunneling states to the charge transport on a macroscopic scale. At temperatures lower than about 20 K, an additional term in the resistivity $\rho(T)$ was detected that frequently exhibited a complex temperature dependence. For other single crystals of ThAsSe, however, a simpler, i.e., a logarithmic increase of $\rho(T)$ upon cooling, followed by a saturation below $T_S \approx 0.2$ K, was found. These peculiarities, together with their independence on both strong magnetic fields and high hydrostatic pressures, point to a Kondo effect derived from structural TLS. Furthermore, some tendency of $\rho(T)$ to pass from a logarithmic to a $-AT^{1/2}$ behavior was observed in a ThAsSe sample with $T_S \approx 0.2$ K, hinting at the development of a possible 2CK state. A crude comparison of the experimental results with the theoretical ones yielded a Kondo temperature of 4–5 K. The presence of tunneling centers in single-crystalline ThAsSe was directly reflected by a quasilinear-in-$T$ term of nonelectronic origin in the low-$T$ specific heat. TLS centers are apparently located in the As-Se substructure, as suggested by x-ray and transmission-electron-microscopy studies as well as $^{77}$Se NMR measurements.

This Letter reports the observation of a 2CK state originating from a scattering of the conduction electrons off structural TLS in ThAsSe. All experiments have been performed on the same single crystal. The synthesis procedure is described in Ref. Due to the platelike...
shape of the crystal, its transport properties have been investigated in the ab plane only. The thermal conductivity was measured in a $^3$He–$^4$He dilution refrigerator utilizing a steady-state method. The electrical resistivity was studied in zero and applied magnetic fields up to 14 T using different equipment below and above 4 K. The specific heat was measured in a $^3$He cryostat with the aid of a thermal-relaxation method.

It is well established that TLS determine the low-temperature thermal properties of matter with some kind of disorder, leading to anomalous terms in the temperature dependences of both the thermal conductivity and the specific heat of comparable magnitude. The low-$T$ thermal properties of ThAsSe are remarkably similar to those of amorphous solids: Fig. 1(a) shows the temperature dependence of the thermal conductivity $\kappa(T)$ of ThAsSe. The electronic contribution $\kappa_{el}^{WF}$ was estimated from the electrical resistivity using the Wiedemann-Franz law. Since for $T \lesssim 1$ K, $\kappa_{el}^{WF}$ (dotted line) is distinctly smaller than the measured total $\kappa(T)$, the heat transport is dominantly carried by phonons. This becomes also evident by comparing the $\kappa(T)$ data of ThAsSe with the published ones for the dielectric glass $\text{As}_2\text{S}_3$ [22, 23] — a prototype of pnictogenchalcogenide-based TLS materials. For $T < 0.7$ K, $\kappa(T)$ of $\text{As}_2\text{S}_3$ follows the relation $\kappa(T) = C(T/\alpha)^\beta$ with $\alpha = 1$ K, $\beta = 1.92$ and $C = 17 \times 10^{-4}$ W/Kcm [23]. A universal power-law dependence of $\kappa(T)$ with $\delta = 1.9\pm0.1$ is characteristic for systems whose dominating phonon thermal conductivity is limited by scattering from TLS. For ThAsSe, $\kappa(T)$ can be well described, below 0.8 K, by the same relation with $\alpha = 1$ K, $\beta = 1.97$ and $C = 23 \times 10^{-4}$ W/Kcm (cf. solid line). While the exponent $\delta$ fits perfectly into the narrow range $1.9\pm0.1$, the value of $C$ is only slightly larger than that for the vitreous $\text{As}_2\text{S}_3$ (part of this difference may be well attributed to errors in the estimation of the geometric form factor of the ThAsSe crystal). Furthermore, phonon scattering off conduction electrons, leading also to a $T^2$-contribution to $\kappa(T)$, seems to be negligible in ThAsSe: the product of the mean free path of the charge carriers, $l_c$, and the wave number of the dominating phonon, $q_{ph}$, is estimated to be 0.5, i.e., below the so-called Pippard ineffectiveness condition $l_c q_{ph} = 1$ [23]. Thus, the low-$T$ thermal conductivity provides striking evidence for the TLS being the dominating scattering centers for the propagating phonons in ThAsSe.

Additional evidence for tunneling centers in ThAsSe comes from the low-$T$ specific heat results in Fig. 1(b). Here, we compare $C(T)$ of our ThAsSe crystal with $C(T)$ previously obtained for an ensemble of small single-crystalline pieces of this material [18]. Though quantitatively slightly different, the two sets of data confirm the existence of an anomalous term, $\sim T$, to the specific heat. At low temperatures, this term adds to the specific heat due to charge carriers and phonons, $\gamma T + \beta T^3$, determined at 1.7 K $< T <$ 5 K. The additional low-$T$ contributions is ascribed to the presence of TLS.

Having established the glassy character of the ThAsSe single crystal studied, we now turn to the discussion of its electronic transport properties at low temperatures. As shown in Fig. 2, an additional contribution to $\rho(T)$ emerges at temperatures below 16 K. Here we plotted the relative change of the resistivity normalized to the corresponding value at 1 K, $\Delta \rho/\rho_{1K}$. For $T \lesssim 0.9$ K and $B = 0$, the resistivity is seen to level off. By applying a magnetic field larger than $B = 1$ T, $\rho(T)$ depends strictly linearly on $T^{1/2}$ in a wide temperature window, i.e., from around 0.16 K to above 12 K at $B = 14$ T. The coefficient of the $-A T^{1/2}$ term amounts to $A = 0.38 \mu\Omega\text{cm}/K^{1/2}$ for all fields $B \geq 1$ T. [Here, we assumed $\rho_{ab}(300 \text{ K}) = 220 \mu\Omega\text{cm}$ 24, see also Fig. 3(c).] Finally, we note that, while this anomalous contribution to the resistivity sets in at slightly lower temperatures with increasing $B$ (cf. arrows in Fig. 2), $\rho(T)$ begins to saturate – independently of $B$ – at the same temperature below 0.1 K 27.

The field-independent $T^{1/2}$ increase of $\rho(T)$ observed upon lowering the temperature can neither be attributed to weak localization 25 nor to electron-electron interactions in a three-dimensional disordered system 26. In fact, both type of quantum corrections to the resistivity are highly sensitive to magnetic fields, which holds true even in the presence of strong spin-orbit coupling 25, 26. For example 30, the interference of the wavefunctions of the electrons moving along a closed loop is
shown in Fig. 3(a) as \( \rho \) becomes smaller, the isothermal response of the resistivity being suppressed already by a field \( B \leq 1 \) T in the weak field limit is hidden by another phenomenon. Therefore, we suppose that the 2CK effect around 1.3 K, already weakened or even destroyed by a magnetic field of the order of tens of an Oe only. We, therefore, attribute the field-independent \(-AT^{1/2}\) term in the electrical resistivity to electron scattering off the TLS, whose existence had been estimated by the thermal measurements described above. This is, to our knowledge, the first-ever observation of the 2CK state originating from TLS in a macroscopic system.

Within the scope of electron-TLS interaction, an increase of the zero-field resistivity upon cooling, being weaker than \(-AT^{1/2}\) as measured for \( B \neq 0 \) (Fig. 2), is somewhat surprising. This holds true also for the strong field dependence of \( \rho(T) \) at the lowest temperatures for \( B<1 \) T (Fig. 2): while some deviations from \( A=0.38 \mu \Omega \text{cm/K}^{1/2} \) are still visible in \( B=0.2 \) T below around 1.3 K, already \( B=1 \) T acts in the same way as 7 and 14 T do. Therefore, we suppose that the 2CK effect in the weak field limit is hidden by another phenomenon being suppressed already by \( B \approx 1 \) T. To explore this possibility further, the isothermal response of the resistivity to a magnetic field was studied.

The magnetoresistivity (MR) data for ThAsSe are shown in Fig. 3(a) as \( (\rho_B - \rho_0)/\rho_0 \) vs \( B^{1/2} \). The measurements were performed in the temperature window 0.1 K \( \leq T \leq 10 \) K where the \(-AT^{1/2}\) dependence was observed in \( \rho(T) \). A positive MR whose magnitude gradually decreases with increasing temperature is found at \( B<1 \) T only. At \( T=10 \) K, \( (\rho_B - \rho_0)/\rho_0 \) is practically zero in this field range. This low-field effect hints at some quantum corrections. Most probably, the positive magnetoresistivity reflects spin-orbit scattering that rotates the spin of the conduction electrons and yields a destructive interference of the electron wavefunctions. Consequently, the differences between the results obtained at \( B \leq 0.2 \) T and those obtained at \( B \geq 1 \) T, as depicted in Fig. 2, are tentatively ascribed to quantum corrections.

Further arguments against the interference effects in higher fields derive from the data at \( B \geq 1 \) T, where the MR is negative. Because of the \( T \)-independent slope of \( (\rho_B - \rho_0)/\rho_0 \) vs \( B \) curves displayed in Fig. 3(a) for \( B \geq 1 \) T, this negative MR cannot be ascribed to weak localization. Furthermore, at fields of the order of \( (2\mu_B/k_B T)^{-1} \), one should expect a deviation from the observed \( B^{1/2} \) behavior due to the electron-electron interaction, which is not resolved in the data of Fig. 3(a).

A small and negative MR appears to be characteristic for ThAsSe [Fig. 3(b)]. However, the MR decreasing as \( B^{1/2} \) has been observed only at \( T \leq 10 \) K. Additionally, the slope of the isothermal \( B^{1/2} \) dependence accounts for 0.77 \( \mu \Omega \text{cm/T}^{1/2} \) and is by a factor of 2 larger than the \( A=0.38 \mu \Omega \text{cm/K}^{1/2} \) coefficient obtained in constant \( B \). Though not yet understood, this relationship between the negative MR and the occurrence of the extra \(-AT^{1/2}\) term in \( \rho(T) \) found for \( T \leq 12 \) K and \( B \geq 1 \) T (cf. Fig. 2) is very intriguing. Both observations, however, confirm the existence of a characteristic energy scale of a few K in ThAsSe. We note that a negative MR is also expected for a 2CK effect originating from electrical quadrupole moments.

Recent examinations of ThAsSe revealed a strong sample dependence of its resistivity in the high temperature...
region \[18\]. This is due to a different amplitude of the increase of \(\rho(T)\) with decreasing temperature down to around 65 K. Indeed, all the \(\rho(T)\) dependencies can be mapped to the same \(\rho(T)/\rho_{300K}\) curve, as demonstrated in Fig. 3(c). Here we compare the normalized resistivity for the ThAsSe single crystal studied (\(\rho_{4K}/\rho_{300K}=1.99\)) with that one for the sample characterized by the lowest resistivity ratio (1.38) measured previously \[18\]. Since our treatment does not affect the temperature scale, the observed sample dependence in ThAsSe has clearly a quantitative character only.

The negative temperature coefficient of the resistivity above 65 K originates, most likely, from a gradual formation of covalently bonded dimers (As-As)\(^{4-}\) \[22\]. The latter ones have been recently observed by means of an electron diffraction study \[32\]. In such a case, the degree of dimerization, being sensitive to crystal growth conditions, may be responsible for the varying \(\rho_{4K}/\rho_{300K}\) values. Nevertheless, the formation of (As-As)\(^{4-}\) does not affect the low-energy physics in ThAsSe for the following reasons: First, virtually identical electron diffraction patterns have been obtained at 30 and 100 K \[32\]. Second, a qualitatively different response of the resistivity to the application of high pressure has been observed at low and high temperatures: At 1.88 GPa the maximum of the resistivity at 65 K is suppressed, whereas the low-\(T\) term is completely unchanged \[18\].

As far as the formation of tunneling centers is concerned, it is, however, conceivable that some low-energy excitations of singular (As-As)\(^{4-}\) dimers play an important role. A more exciting possibility concerns the fact that some pnictogen atoms As and chalcogen atoms Se become involved in a homopolar-to-heteropolar bond transformation, as discussed for As\(_2\)Se\(_3\) \[32\] and As\(_2\)S\(_3\) \[32\]. The latter scenario is even more plausible for non-stoichiometric samples \[32\]. In other words, we speculate that the movable particle is an electron, tunneling between As and Se, rather than an atom: \(T_K\) of a few K in ThAsSe would then be the consequence of the electron mass being smaller than the atomic masses by about four orders of magnitude.

In summary, we have investigated a ThAsSe single crystal whose low-temperature resistivity shows a -\(AT^{1/2}\) behavior. Its origin was found to be very different from the frequently observed quantum interference \[25\, 26\, 27\], as highlighted by the independence of the resistivity on strong magnetic fields. Furthermore, the low-\(T\) thermal properties give clear evidence for the presence of tunneling centers in the sample studied. Our experimental findings lead to the suggestion of a two-channel Kondo effect originating from interactions between the conduction electrons and TLS. We hope that our results will have a significant impact on this interesting field of research, given the fact that the existence, in real matter, of a two-channel Kondo regime due to tunneling particles is still a matter of strong current controversy \[9,17\].

We would like to express our gratitude to A. Zawadowski for many enlightening discussions. We are also grateful to A. Bentien, S. Wirth, and G. Zaránd for valuable conversations, and the Polish Committee for Scientific Research, Grant No. 1 P03B 073 27 (T.C., A.W., and Z.H.) for support.
