Abstract: Dried colonies of the Antarctic rock-inhabiting meristematic fungi Cryomyces antarcticus CCFEE 515, CCFEE 534 and C. minteri CCFEE 5187, as well as fragments of rocks colonized by the Antarctic cryptoendolithic community, were exposed to a set of ground-based experiment verification tests (EVTs) at the German Aerospace Center (DLR, Köln, Germany). These were carried out to test the tolerance of these organisms in view of their possible exposure to space conditions outside of the International Space Station (ISS). Tests included single or combined simulated space and Martian conditions. Responses were analysed both by cultural and microscopic methods. Responses were analysed both by cultural and microscopic methods. Thereby, colony formation capacities were measured and the cellular viability was assessed using live/dead dyes FUN 1 and SYTOX Green. The results clearly suggest a general good resistance of all the samples investigated. C. minteri CCFEE 5187, C. antarcticus CCFEE 515 and colonized rocks were selected as suitable candidates to withstand space flight and long-term permanence in space on the ISS in the framework of the Lichens and Fungi Experiments (LIFE programme, European Space Agency).

Key words: Astrobiology, cryptoendolithic community, fungi, ground-based experiments, lithopanspermia, panspermia, space conditions, stress resistance, viability.

INTRODUCTION

Astrobiology raises the fascinating question about the possible existence of life forms on other planets, survival in space conditions and possible interplanetary transfers. This emerging field of research encounters evident challenges in carrying out in situ experiments. Most of the information on the behaviour of organism under extraterrestrial conditions has been obtained by space simulation experiments performed on Earth (Nicholson et al. 2000, Rettert et al. 2004, de Vera et al. 2003, 2004). Earth is our only reference for studying the possibility of life on other planetary bodies: extreme terrestrial environments host specifically adapted organisms, among which anhydrobionts are generally considered the best models for exobiological studies (Finster et al. 2007). Extreme environments include the cold and dry polar regions, permafrost soils, deep sea, alkaline and hypersaline habitats, arid regions, or acidic sites (González-Toril et al. 2003, McKay et al. 2003, Gunde-Cimerman et al. 2005, Gilichinsky et al. 2007, Onofri et al. 2007a). Organisms able to thrive in extreme environments are generally defined as "extremophiles". The existence of extremophiles has led to speculations about the survival of organisms during interplanetary transfer and that life could be present even on other planets of the Solar system, where water might be present e.g. under the icy surfaces of some of Jupiter’s moons or in the underground caverns of Mars (Miller 2005, Mustard et al. 2008).

Antarctica is a continent where a combination of dry, cold, and oligotrophic extremes exists, and huge fluxes of dangerous radiations such as UV radiation can be present as well. These conditions become harsher in the ice-free McMurdo Dry Valleys area in continental Antarctica where cryptoendolithic microbial communities are almost the only life-form possible. Black meristematic microfungi of these communities were already suggested as eukaryotic models for the biological exploration of Mars (Onofri et al. 2004). The McMurdo Dry Valleys area, also known as Ross Desert, is the largest ice-free area in Antarctica. It is located within the Transantarctic Mountains in the Southern part of Victoria Land. Winter air temperature fluctuates between −20 and −50 °C (occasionally lower), rising to mean daily values of about −15 °C in the summer, up to 15 °C or higher values at ground surfaces. Wide and repeated thermal fluctuations are a stress factor, more than the minimum values reached. Dryness is also extreme: water is mainly supplied by snow (less than 100 mm water equivalent / yr), that mostly sublimes without visibly wetting the ground or it is blown away (Nienow & Friedmann 1993). High evaporation leads to high salt concentration on rock surfaces and a poor nutrient soil is occasionally present because of the scarcity of organic matter. Finally, UV radiation is high, mainly in the springtime, as a consequence of stratospheric ozone depletion during this period. As for its oxygenic atmosphere no place on Earth is truly comparable to what is present on Mars, the McMurdo Dry Valleys could be called the closest terrestrial analogue. Therefore, they are one of the best investigated areas as a model environment for astrobiological studies since the 1970ies (Horowitz et al. 1972, Wynn-Williams & Edwards 2000, Onofri et al. 2004).

Friedmann and co-workers (Friedmann & Ocampo-Friedmann 1976, Friedmann 1982, Nienow & Friedmann 1993) discovered various microbial communities in the Ross Desert. The communities live sheltered under the rock surface, where they find a more favorable nanoclimate in the rock pore-spaces. Among these, the "lichen dominated cryptoendolithic community" is the most studied and known (Friedmann 1982). Under a reddish superficial crust, eukaryotic and prokaryotic autotrophic and heterotrophic microorganisms form a clearly stratified community. Antarctic black non-lichenised rock fungi, showing meristematic growth, are recurrent components of this community and common
inhabitants of the black zone immediately below the lichen crust. Their biodiversity has been studied only recently. Sampling is still limited, yet some new genera were discovered in these habitats, viz. *Friedmanniomyces*, *Cryomyces*, *Recurvomyces* and *Elasticomyces* (Onofri et al. 1999, 2004, Selbmann et al. 2005, 2008).

The results from freeze-thaw experiments, after UV exposures and osmotic stress tolerance of two isolates of *C. antarcticus* (CCFEE 515 and CCFEE 534 = CBS 116301), and one isolate of *C. minteri* (CCFEE 5187 = CBS 116902), revealed an unusual ability to survive under these pressures (Onofri et al. 2007b).

The opportunity to expose these isolates to space conditions by the “EXPOSE-E” facility of the European Space Agency (ESA) on the EuTEF platform (part of the European Columbus Laboratory) outside of the International Space Station (ISS) inspired ground-based experiments that will be described in this contribution. The experiments have been carried out at the German Aerospace Center (DLR, Köln, Germany), where we tested single and combined simulated space and Martian conditions. Furthermore, we extended the experiments to the entire Antarctic cryptoendolithic community as well, also to test the potential protective role of the rock substratum.

We considered this as a preliminary and essential step before launching Antarctic black fungi and cryptoendolithic communities to outer space and for exposure on the ISS in the framework of the Lichens and Fungi Experiments (LIFE, European Space Agency).

### MATERIALS AND METHODS

#### Biological material

The biological material used for the Experiment Verification Tests (EVTs) consisted of two isolates of *C. antarcticus* (CCFEE 515 and CCFEE 534), one isolate of *C. minteri* (CCFEE 5187), and colonised rock fragments.

* Cryomyces antarcticus* CCFEE 515 was isolated by R. Ocampo-Friedmann from sandstone collected at Linnaeus Terrace (Southern Victoria Land) by H. Vishniac, in the Antarctic expedition 1980–81; *C. antarcticus* CCFEE 534 was isolated by R. Ocampo-Friedmann from weathered rock collected at Linnaeus Terrace by E.I. Friedmann, during the Antarctic expedition 1981–82; *C. minteri* CCFEE 5187 was isolated by S. Pagano from weathered rocks collected by S. Onofri at Battleship Promontory (Southern Victoria Land) on Dec 28, 1996. For the EVTs, dehydrated fungal colonies were prepared as follows: cell suspensions were spread on MEA (malt extract agar: malt extract, powdered 30 g/L; peptone 5 g/L; agar 15 g/L; Applichem, GmbH) medium (5 mm thick) in Petri dishes and, once grown, maintained at 15 °C for 1 yr. Agar disks (12 mm diameter) containing 1–3 colonies each were then drilled and used for tests.

The colonised sandstone sample, with a well developed and stratified colonisation, was collected by L. Zucconi at Battleship
Promontory (76°54'37.6"S 160°55'27.5"E), Southern Victoria Land, on Jan. 24, 2004. Colonised rock fragments (11 mm wide, maximum 6 mm thick) were obtained by hitting the rock lengthwise, and then dehydrated at room temperature.

Tests facilities and exposure conditions

Two sets of ground-based Experiment Verification Tests for EXPOSE-E (EVT-E1 and EVT-E2) were performed, using the Planetary and Space Simulation facilities (PSI) at the Institute of Aerospace Medicine (German Aerospace Center, DLR, Köln, Germany). Twenty-seven samples of each isolate and colonised rock for the EVT-E1 (9 tests) and 12 for the EVT-E2 (4 tests) were prepared, plus 3 controls each. The aim of EVT-E1 was to test the response of rock fungi and cryptoendolithic communities to exposure to the following space conditions: vacuum, temperature fluctuations (–20 / +20 °C), laboratory standard monochromatic UV-C radiation and high polychromatic UV radiation (Table 1). The aim of EVT-E2 was to test the responses of rock fungi and cryptoendolithic community to simulated space vacuum, simulated CO₂ Martian atmosphere and pressure, simulated space vacuum combined with polychromatic UV radiation, and simulated CO₂ Martian atmosphere combined with polychromatic UV radiation (Table 1). All tests were performed in triplicate.

Vacuum (E1 and E2)
The pressure was set at the value of 10⁻⁵ Pa as expected to prevail during the space flight. Samples were accommodated in a vacuum facility, called PSI 6, and exposed to vacuum for 1 h and 1 wk for E1, and 22 d for E2, after reaching 10⁻⁵ Pa (monitored by a Pirani cold cathode inserted into the vacuum chamber).

Temperature fluctuation (E1)
Temperature fluctuations (–20 / +20 °C) are expected during the space flight. 50 cycles were therefore performed inside a facility, called PSI 2, within 2 wk, programming 2 h heating, 2.5 h cooling, and maintenance at –20 °C and +20 °C respectively for 1 h. The temperature was monitored with a sensor attached to the inner side of a sample carrier.

UV Radiation conditions and fluences (E1 and E2)
E1. The monochromatic UV-C at 254 nm was obtained using a Hg-low-pressure lamp, mainly emitting at 254 nm (data provided by DLR). The polychromatic UV irradiance was obtained using the solar simulators SOL2000 and SOL1000 (the latter only used in EVT-E2). Figs 2–3 show only the polychromatic UV irradiation spectra in the range 200–400 nm. The samples were accommodated on a cold plate inside the homogeneously irradiated area inside the facility PSI 2 (Fig. 4), and kept below 30 °C during the whole irradiation, by cooling the cold plate to 10 °C. Temperature was monitored during the irradiation by a sensor attached to the sample carrier (Fig. 5). The fluences for irradiation with polychromatic UV in EVT-E1 were selected to simulate the final dose of irradiation (1.5 × 10⁵ kJm⁻²) and the attenuated fluences beneath 1 % and 0.01 % neutral density filters, expected on the ISS during the mission in this wavelength range. Similar fluences were reached with the solar simulator SOL2000 after 87 h irradiation for 1.5 × 10⁵ kJm⁻², 52 min for 1.5 × 10⁴ kJm⁻² and 3 s for 1.5 kJm⁻² (Table 1).
Responses to test parameters were analysed both by cultural and staining methods. Viability of isolates of C. antarcticus (CCFEE 515 and CCFEE 534) and of C. minteri (CCFEE 5187) after EVTs by cultural methods was evaluated as number of formed colony. Tested colonies were collected, preliminarily treated in a rotator (9 g/min) with 1 mL of a sterile solution of Tween 20 (0.35 %) for 15 min to remove eventual external contaminants, and then washed with 1 mL of sterile physiological solution (4 times), for 15 min, to remove Tween 20. Fungal suspensions were obtained by crumbling colonies with a sterile needle, followed by serial dilutions up to a final concentration of about 10^3 cells per mL of inoculum in physiological solution (0.9 % NaCl). Cultural tests were performed by spreading 0.15 mL of standardised inocula on MEA (Malt Extract Agar, Applichem GmbH), with the addition of chloramphenicol (100 ppm) to prevent bacterial growth. Cultures were then incubated at 15 °C. The number of growing microcolonies was recorded after 1 and 2 mo of incubation. Data are reported as percentage of colonies compared to the untreated control. All tests were performed in triplicate.

Viability of samples from rocks was demonstrated by directly spreading small fragments of rocks on 5 different cultural media: MEA (Malt Extract Agar; Applichem GmbH) and DRBC (Oxoid) media (Dichloran Rose-Bengal Chloramphenicol agar: peptone 5 g/L; dextrose 10 g/L; biacid potassium phosphate 1 g/L; magnesium sulphate 0.5 g/L; dichloran 0.002 g/L; rose-bengal 0.025 g/L; agar 15 g/L) for fungal growth; TY and B111 media (Trypton Yeast Medium: trypton 5 g/L; yeast extract 3 g/L; CaCl₂ anhydrous 0.4 g/L; agar 17 g/L). Blue Green Algae Medium: NaNO₃ 1.5 g/L; KH₂PO₄ 0.04 g/L; MgSO₄ × 7H₂O 0.075 g/L; CaCl₂ × 2H₂O 0.036 g/L; citric acid 0.006 g/L; ammonium ferric citrate 0.006 g/L; EDTA 0.001 g/L; metal traces 1 mL/L: H₃BO₃ 2.86 g/L; MnCl₂ × 4H₂O 0.18 g/L; ZnSO₄ × 7H₂O 0.222 g/L; NaMoO₄ × 2H₂O 0.39 g/L; CuSO₄ × 5H₂O 0.079 g/L; Co(NO₃)₂ × 6H₂O 49.4 mg/L; agar 10 g/L) for bacterial and cyanobacterial growth, respectively. The occurrence / absence of growing colonies was simply recorded after 3 mo of incubation in the dark for fungi and bacteria, and in the light for algae and cyanobacteria.

Viability was also evaluated by staining methods using two dyes, the LIVE / DEAD dye FUN 1 (30 µM) and SYTOX Green (10 µM) in PBS (Dulbecco’s Phosphate Buffered Saline: NaCl 8 g/L; KCl 0.2 g/L; Na₂HPO₄ anhydrous 1.15 g/L; KH₂PO₄ 0.259 g/L). This enabled us to detect viable and metabolically active cells as well as non-viable or damaged cells. Staining methods were applied only to Cryomyces minteri isolate.

Each tested colony was rehydrated with a PBS solution for 1 h, included in a polyethylene glycol mixture (Killik, Bio-Optica) inside a cryostat chamber (Leica, CM1510 S) at ~20 °C for 10 min, cut into sections about 25 µm thick by a microtome, and coloured on microscope slides. The best dye penetration for FUN 1 and SYTOX Green was obtained with an incubation of 1–3 h and 1.5 h respectively, under dark conditions at room temperature.

A fluorescence microscope Axioskop 2 plus (Zeiss), provided with long-pass filters (488 nm with emission ≥ 530 nm for fluorescein isothiocyanate, 546 nm with emission ≥ 580 nm for the rhodamine), was used to analyse the viability of the C. minteri samples after exposure to test parameters. Red (viable and metabolically active) and green (viable but not metabolically active) emitting images of stained samples were separately acquired by a mounted Axiocam.
90 °C was also evaluated in colonies for tests at 80 and 90 °C. Viability after exposure at 80 and 15 °C, for the tests at 60 °C, and as presence/absence of growing (5 replicates). All colonies were subsequently maintained overnight. *C. minteri* CCFEE 5187 were incubated for 60 min at 80 and 90 °C.

*C. minteri* *Cryomyces antarcticus* by the vacuum treatment, more markedly in as percentage variations, compared to the untreated controls, in (EVT-E2) of exposure to simulated space vacuum is reported. The viability of dried isolates after 1 h, 1 wk (EVT-E1) and 22 d (EVT-E2) of exposure either to vacuum or Martian CO₂, and a reduction, but not complete inhibition, at combined UV radiation and Martian atmosphere. A total absence in viability apparently appears in the combined test of vacuum and maximum UV (200–400 nm) dose of 1.5 × 10⁵ kJ m⁻², but this result was disproved by the staining techniques.

**RESULTS**

**Fungal isolates**

Figure 6 shows cell viability of fungal isolates after Experiment Verification Tests E1 and E2, analysed by cultural methods.

**Vacuum**

The viability of dried isolates after 1 h, 1 wk (EVT-E1) and 22 d (EVT-E2) of exposure to simulated space vacuum is reported as percentage variations, compared to the untreated controls, in the number of colonies grown after 2 mo of incubation on MEA at 15 °C, for the tests at 60 °C, and as presence/absence of growing colonies for tests at 80 and 90 °C. Viability after exposure at 80 and 90 °C was also evaluated in *C. minteri* by staining methods.

**Freeze and thawing cycles**

Results of the viability of dried isolates after 50 repeated freeze and thawing cycles, recorded as above and compared to the untreated controls, showed different responses. *C. antarcticus* CCFEE 515 was the most negatively affected with a strong reduction of growth ability, *C. minteri* CCFEE 5187 showed a 75 % reduction, while *C. antarcticus* CCFEE 534 seemed to be almost unaffected.

**UV radiation at different spectral ranges**

With respect to the capability of dried fungal isolates to form colonies after increasing monochromatic or polychromatic radiation doses, respectively, *C. antarcticus* isolates were both negatively affected by the higher doses of polychromatic UV, whereas the species showed diversified response to the monochromatic irradiation (Fig. 6). CCFEE 515 remained practically unaffected, and CCFEE 534 was totally inhibited after the highest exposure only. *Cryomyces minteri* CCFEE 5187 showed a good survival after both radiation types and doses, with a certain decrease only at the highest doses.

**UV radiation plus vacuum or Martian atmosphere and pressure**

Figure 6 shows the results of exposure of dried samples to polychromatic UV spectrum in space-simulating vacuum as well as in simulated Martian atmosphere compared to vacuum and Martian atmosphere exposure, respectively. Growth obtained with both isolates of *C. antarcticus* was scarce, with a complete inhibition of isolate CCFEE 534 and a substantial reduction in viability in CCFEE 515. This response was consistent with negative results obtained after vacuum and 1.5 × 10⁴ kJ m⁻² polychromatic irradiation. Propagules of *C. minteri* CCFEE 5187 showed a higher survival than both *C. antarcticus* strains after exposure either to vacuum or Martian CO₂, and a reduction, but not complete inhibition, at combined UV radiation and Martian atmosphere. A total absence in viability apparently appears in the combined test of vacuum and maximum UV (200–400 nm) dose of 1.5 × 10⁴ kJ m⁻², but this result was disproved by the staining techniques.

The LIVE / DEAD dye FUN1 (F-7030, Molecular Probes) passively penetrates the cytoplasm and stains cells with a yellowish green to green fluorescence: the intravacuolar enzymatic activity of viable and metabolically active cells is indicated by the appearance of compact cylindrical intravacuolar structures (CIVS) with an orange to red fluorescence (when a λₑₓ between 470 and 590 nm is used) and a concomitant reduction of the green to yellow cytoplasmatic fluorescence.

The staining procedure failed with the isolates of *C. antarcticus* because the thickness of cell wall prevented the penetration of the dyes, while the same procedure was successful with *C. minteri*. Good viability percentages obtained in all EVTs with the LIVE / DEAD dye FUN 1 (Fig. 7) confirmed the positive responses obtained by the cultural methods and the high resistance of *C. minteri* to simulated space and Martian conditions in both EVTs, while combined vacuum and maximum UV (200–400 nm) exposure gave ambiguous results when the responses were tested with cultural or staining approach. In fact, even though *C. minteri* was unable to grow after this treatment, cell viability in a 25 µm section of a colony was suggested by the red and green fluorescence shown in Fig. 8. Data (not shown) obtained by the SYTOX Green dye, confirmed results reported in Fig. 7.
Fig. 6. Percentage variations, compared to untreated control, in the number of colonies of *C. antarcticus* CCFEE 534 and CCFEE 515 and *C. minteri* CCFEE 5187 after exposure to single or combined simulated space and Mars conditions (EVT-E1 and E2), evaluated by cultural methods.

Fig. 7. Percentage variations, compared to untreated control, of *C. minteri* CCFEE 5187 cell viability after experiment verification tests E1 and E2, evaluated *in vivo* by LIVE/DEAD dye FUN 1.
Fig. 8. Red and green fluorescence of viable and metabolic active cells in 25 µm sections of a *C. minteri* colony treated with LIVE / DEAD dye FUN 1, after combined exposure to vacuum and maximum polychromatic UV 200–400 nm dose (bar = 50 µm).

Fig. 9. Percentage variations, compared to controls, in the number of colonies of *C. antarcticus* CCFEE 534 and CCFEE 515 and *C. minteri* CCFEE 5187 after incubation at 60 °C for 15 and 60 min.

Fig. 10. Colonies on MEA of *C. minteri* CCFEE 5187 and *C. antarcticus* CCFEE 515 after incubation at 80 °C (center) and 90 °C (right) for 60 min, compared to the controls (left).
Effect of incubation at 60 °C for 15 and 60 min, and of 80 and 90 °C for 1 h respectively, on the viability of the tested isolates, was evaluated by counting the number of colonies (Fig. 9) and the presence / absence of grown colonies (Fig. 10). A good resistance of all strains was found at 60 °C for both 15 min and 60 min, with low variations compared to the controls. Both tested isolates of *C. minteri* CCFEE 5187 and *C. antarcticus* CCFEE 515 showed an unexpected high viability of growing colonies after exposure to 80 and 90 °C, already after one mo incubation (Fig. 10). Viability of *C. minteri* was confirmed by LIVE / DEAD dye FUN1 staining (Fig. 11).
13 positive responses were recorded for E2. Reporting results as survival (+) or non-survival (-) (Table 3), thirteen verification tests were carried out in both EVT-E1 and space or Martian conditions, despite wide standard deviations. This study demonstrates high resistance of all isolates to simulated concentrations and UV-B irradiation (Onofri et al. 2007b). This study demonstrates high resistance of all isolates to simulated space or Martian conditions, despite wide standard deviations. Thirteen verification tests were carried out in both EVT-E1 and E2. Reporting results as survival (+) or non-survival (-) (Table 3), 13 positive responses were recorded for C. minteri CCFEE 5187, 10 for C. antarcticus CCFEE 515 and 6 for C. antarcticus CCFEE 534. Moreover, results obtained by staining methods in C. minteri (Fig. 7) showed no significant reductions of living cells both in control and treated cultures, with the exception of the UV-C treatment (254 nm, 1000 Jm⁻²). The higher resistance of C. minteri CCFEE 5187 to both EVTs and the good survival shown to heat shocks suggested that this isolate might be selected as a good candidate to withstand space flight and long-term permanence in space. Under the most selective combined condition of vacuum and maximum dose of polychromatic UV used, this strain was unable to grow. Its positive response in staining techniques but absence of growth might be due to the transition to a state of “viable but non-culturable cells” (VBNC), as described for bacteria (Weichart 1999). Apparently cells can maintain their integrity and viability but nevertheless may lose reproductive ability. Growth of C. minteri may escape detection because of the transition to a specific survival state characterised by deceleration of vital activity (DVA) (Feofilova 2003). Because C. antarcticus cells were not stainable, we did not have the opportunity to verify the occurrence of viable but not culturable cells after exposure to stressing conditions. Particularly surprising were the results concerning single and combined irradiation of C. minteri at the maximum UV polychromatic dose, since it corresponds to the irradiation expected during the whole planned space exposure of 1.5 yr without attenuation, i.e. without neutral density filter.

**Cryptendo Lithic community**

Table 2 reports the presence or absence of colonies grown from rock fragment samples after EVTs. Eleven verification tests E1 and E2 were carried out, and colony appearance was recorded in 8 of them. Negative results are those concerning polychromatic irradiation at higher doses and vacuum plus polychromatic UV-irradiation at the lower dose. Some samples treated with simulated Martian atmosphere with or without combined polychromatic UV radiation have been lost and EVT-E2 data for these experiments are missing.

**DISCUSSION**

This is the first report on resistance of fungal isolates and cryptoendolithic communities from terrestrial extreme environments, to simulated space and Martian conditions, which were applied individually or in different combinations. Selected fungal isolates were previously demonstrated to survive some extreme terrestrial factors, such as repeated freezing and thawing cycles, high salt concentrations and UV-B irradiation (Onofri et al. 2007b). These characteristics convey to high tolerance to extreme terrestrial environments and, by coincidence, spacial conditions. Melanin, for instance, is a biological macromolecule, ubiquitous in nature, mainly known for its protective role against UV and ionising radiation, extreme temperatures, and desiccation (Sterflinger 2005). The high resistance to space conditions shown by the three isolates tested could be ascribed to the peculiar morpho-physiological features of black meristematic fungi. These microorganisms produce slowly expanding, cauliflower-like colonies, barely differentiated structures, and thick and heavily pigmented cell walls (Selbmann et al. 2005, Onofri et al. 2007a). These characteristics convey to high tolerance to extreme terrestrial environments and, by coincidence, spacial conditions. Melanin, for instance, is a biological macromolecule, ubiquitous in nature, mainly known for its protective role against UV and ionising radiation, extreme temperatures, and desiccation (Sterflinger 2005). The high tolerance to the UV-B exposure of single cells of the tested fungi has been reported recently (Onofri et al. 2007b). The thickness of the colony itself may represent an additional protection for the cells in the inner layers.

The high resistance to space conditions shown by the three isolates tested could be ascribed to the peculiar morpho-physiological features of black meristematic fungi. (*) Result obtained only by staining techniques.
2005). The ability to enter a cryptobiotic state under poikilohydric conditions could be aided by the presence of abundant extracellular polymeric substances (EPS) in many species. EPS production may be abundant (Selbmann et al. 2005) and may appear as a gelatinous matrix in lichen thalli (de Vera et al. 2004) which may serve as a water reservoir to survive long dry periods (de los Ríos et al. 2004, 2005). Not surprisingly, many meristematic black fungi are commonly recorded from Mediterranean areas and hot deserts, where substrate surface temperatures can reach very high values. The ability to survive long-term desiccation makes these isolates pre-adapted to the extreme conditions of space, since high-vacuum conditions produce an extreme dehydrating effect. Recent studies also show that lichens, as well as their isolated photobionts and mycobionts, cope with the extreme conditions of outer space in ground-based experiments (de Vera et al. 2003, 2004). Xanthoria elegans was able to photosynthesise under simulated Martian conditions with light in visible wave-lengths and in the presence of water (de Vera et al. 2007). Finally, samples of the lichens Rhizocarpon geographicum and X. elegans survived 16 d of exposure to space in the BIOPAN-5 facility of the European Space Agency located on the outer shell of the Earth-orbiting FOTON-M2 Russian satellite (Sancho et al. 2007).

By means of the NASA Space Shuttle Atlantis flight launched on Feb 7, 2008, these fungi are now exposed to actual space in the EXPOSE facility (created by Kaiser-Threde - DE) on the outside platform EuTEF of the International Space Station, orbiting round the Earth at a height of ~300 km, where space conditions include pressures of 10^-5 Pa, temperatures ranges between ~20 and +20 °C, and full solar (including UV-A, UV-B, and UV-C) and cosmic radiation. These conditions are normally prohibitive for life.

Lithopanspermia postulates the feasibility of interplanetary transfer of living material, protected against extraterrestrial solar UV and possibly heat within asteroids, comets and meteories (Nicholson et al. 2000). Our knowledge on the limits of life has largely expanded in the last decades. The discovery of extremophiles, the high survival of Bacillus subtilis spores over 6 yr in space (Horneck et al. 1994), the survival of lichens after ground-based experiments (de Vera et al. 2003, 2004), as well as in space for 2 wk during the Biopan experiments (Sancho et al. 2007), and our results with the Experiment Verification Tests on meristematic fungi and cryptoendolithic communities give additional support to the idea of lithopanspermia. Considering that 1 yr is the minimum flight time estimated for Martian meteorites landing on Earth (Mileikowsky et al. 2000), the eventual survival after 1.5 yr permanence in space planned in the LIFE experiment represents a further contribution in the scenario of interplanetary transfer of life.

ACKNOWLEDGEMENTS

The authors would like to thank PNRA (Italian National Program for Antarctic Research) for supporting samples collection, Italian National Antarctic Museum “Felice Ippolito” for supporting CCFEE (Culture Collection of Fungi From Extreme Environments), the BMWi for financial support of the Astrobiological working group at the Heinrich-Heine-Universität, Düsseldorf (project 50WB0614), ESA (European Space Agency), and DLR (German Aerospace Center) for organising and supporting Experiment Verification Tests.
