1. Introduction

Decays of neutral pseudoscalar mesons into a lepton–antilepton pair and a photon, $P \to e^+e^-$, are among the processes to search for a new light vector boson connected with dark gauge forces [1–3]. An extra $U(1)$ boson is postulated in most extensions of the Standard Model. Recent interest in searches of a light vector boson, in the $O$ (MeV–GeV) mass range, is motivated by astrophysics observations such as the positron and/or electron excesses observed by PAMELA [4], ATIC [5] and H.E.S.S. [6] as well as the narrow 0.511 MeV $\gamma$ ray emission from the galactic bulge observed by INTEGRAL [7].

In one of the simplest scenarios dark matter particles belonging to an additional abelian gauge symmetry are added to the Standard Model (SM). The new symmetry leaves the SM particles unchanged [8,9,3,10]. The associated gauge boson can communicate with the SM through a small mixing in the kinetic term of the QED Lagrangian [11]:

$$\mathcal{L}_{\text{mix}} = -\frac{\epsilon}{2} f_{\mu\nu} f_{\mu\nu},$$

where $\epsilon$ is the mixing parameter. The gauge boson $U$ (also $A'$, $\gamma'$ or $Z_2'$) is often called a dark photon since it can mix with the photon in all processes (examples are shown in Figs. 1b and 1c). Phenomenological arguments [12–14] suggest that the $\epsilon$ parameter must be of the order of $10^{-4}$–$10^{-2}$ and the boson mass $M_U$ below 2 GeV. This estimate is also supported by the astrophysical observations and the constraints imposed by precision measurements such as the anomalous magnetic moments ($g - 2$) of muon and electron [15]. The contribution of the $U$ boson to the $(g - 2)_\mu$ ($l = e, \mu$) (Fig. 1c) is given in [15] by:

$$\Delta(g - 2)_\mu = \frac{\alpha^2}{\pi} \int_0^1 dz \frac{2m_e^2(1 - z)^2}{m_l^2(1 - z)^2 + M_U^2},$$

Investigations of the $M_U$ vs. $\epsilon^2$ parameter space corresponding to the experimentally preferred $(g - 2)_\mu$ value (shifted +3.6$\sigma$ with respect to the SM value [16–18]) are therefore of great importance.

For a $U$ boson with mass less than twice the muon mass the total decay width is for all practical purposes (neglecting higher-order electric, tiny weak interaction contributions from the $U$ boson – $Z_0$ coupling, and the decay to light dark scalars and/or fermions) given by [19,20]:

$$\Gamma_U = \frac{1}{3} g^2 e^2 M_U \sqrt{1 - \frac{4m_e^2}{M_U^2} \left(1 + \frac{2m_e^2}{M_U^2}\right)},$$

where $m_e$ is the electron mass. Such a light $U$ boson can be directly produced in particle accelerators, see e.g. Refs. [19–27]. The idea is to search for narrow structures in the invariant mass spectrum of the lepton–antilepton pair.

The $M_U$ vs. $\epsilon^2$ region corresponding to the measured $(g - 2)_\mu$ value $\pm 2\sigma$ is covered by the data from the BABAR [28], MAMI A1 [29], KLOE-2 [30] and APEX [31] experiments for $M_U$ masses above 100 MeV. On the lower end this preferred region is excluded by the $(g - 2)_\mu$ value for $M_U < 30$ MeV [32,33]. In addition, $\epsilon^2$ regions below $10^{-12}$ are excluded by experiments which are sensitive to lepton pairs from displaced secondary vertices $(\tau_U > 10^{-11}$ s) [34–36].

Our experiment aims at searching for a short-lived $U$ boson in the $\pi^0$ Dalitz decay, $\pi^0 \to e^+e^-\gamma$, covering the range preferred by the experimental value of $(g - 2)_\mu$ for 20 MeV < $M_U$ < 100 MeV. In this region, for $\epsilon^2 > 10^{-6}$ the average distance passed by a boson emitted from a low energy $\pi^0$ decay should be less than a millimeter. The best limit from a previous $\pi^0 \to e^+e^-\gamma$ experiment with the origin of the $e^+e^-$ pair close to the production vertex was obtained by the SINDRUM collaboration more than twenty years ago [37,38]. The SINDRUM result is based on a sample of $98\,400$ $\pi^0 \to e^+e^-\gamma$ decays with $e^+e^-$ invariant masses above 25 MeV.

2. The experiment

The WASA detector setup was built and first used at CELSIUS in Uppsala and moved to COSY (Cooier SYNchrotron) Jülich in the Summer of 2005 [39]. The detector was designed and optimized for studies of rare $\pi^0$ meson decays produced in $pp \to pp\pi^0$ reaction [40]. It consists of three main components:

- The Forward Detector (FD) – covering scattering angles in the $3^\circ$–$18^\circ$ range used for tagging and triggering of meson production, the Central Detector (CD) – used for measuring meson decay products, and the pellet target system. The target beam consists of 20–30 μm diameter pellets of hydrogen, providing an areal target density in the order of $10^{15}$ atoms/cm$^2$. The diameter of the pellet beam is $\sim 3.8$ mm.

- The CD surrounds the interaction region and is designed to detect and identify photons, electrons, and charged pions. It consists of an inner drift chamber (MDC), a superconducting solenoid providing the magnetic field for momentum determination, a barrel of...
thin plastic scintillators (PS) for particle identification and triggering, and an electromagnetic calorimeter. The amount of structural material is kept to a minimum to reduce the amount of secondary interactions outside of the detector sensitive volumes. The beryllium beam pipe (diameter 6 cm) wall is 1.2 mm thick and the material of the superconducting solenoid corresponds to 0.18 radiator lengths.

The FD allows identification and reconstruction of protons from the \( pp \rightarrow pp\pi^0 \) reaction close to threshold. The track coordinates are provided by four sets of straw proportional chambers. Kinetic energies are reconstructed using the \( \Delta E \) information in layers of plastic scintillators of different thickness. In addition, the signals are used for triggering. The kinetic energy, \( T \), of the protons can be reconstructed with a resolution of \( \sigma (T)/T \sim 1.5\% \) for kinetic energies below 400 MeV.

The results presented here are based on data collected during one-week WASA-at-COSY run carried out in 2010. The \( \pi^0 \) mesons were produced in proton–proton interactions at a kinetic beam energy of 550 MeV. The beam energy corresponds to the center-of-mass excess energy of 122 MeV with respect to \( pp\pi^0 \) threshold (i.e. below two pion production thresholds) with a cross section of 1.12 mb [41]. The maximum scattering angle of the outgoing protons for the reaction is 45°. For detection and for triggering purposes the phase space of the \( pp \rightarrow pp\pi^0 \) reaction can be divided into three regions:

1. Both protons are measured in the FD. This corresponds to a geometrical acceptance of 19%.
2. One proton is measured in the FD and one in the forward part of the PS (scattering angles 20°–40°). This corresponds to a geometrical acceptance of 42%.
3. Both protons are registered in the PS. This corresponds to a geometrical acceptance of 21%.

Case (1) allows the definition of the most selective trigger condition and the best resolution in the missing mass with respect to the two protons. Therefore, the main trigger for the experiment required two tracks in the FD. The protons from the \( pp \rightarrow pp\pi^0 \) reaction have a maximum kinetic energy of 350 MeV and are mostly stopped in the FD. This allows the inclusion of a veto from a thin plastic detector layer placed at the far end of the FD into the trigger condition. In addition, two hits in the central part of the PS (scattering angles 45°–135°) were required, aiming to select the electron–positron pair. An additional, scaled down, trigger based on case (2) was used in parallel. The WASA-at-COSY data acquisition system allowed the collection of more than 10^8 events per second and the luminosity was set to optimize the conditions for the main trigger. The integrated luminosity of the run was about 0.55 pb⁻¹.

The data quality is illustrated by the analysis of the main trigger data sample and requesting in the analysis two identified from the invariant mass of the decay products after this cut is shown in Fig. 2b. The corresponding distribution of \( MM(pp) \) after electron identification: experimental data (black points) and sum of Monte Carlo simulations (solid line). c) The reconstructed invariant mass of the \( e^+e^- \) system after particle identification cut.

\]
The form factor close to the dilepton momentum in the overall perturbed $\pi$ decay, where in the latter case one of the two photons converts in the beryllium beam tube.

For Monte Carlo simulations, angular distributions for the $pp \rightarrow pp\pi^0$ reaction from [41] were used in the event generation. The $\pi^0 \rightarrow e^+e^-\gamma$ decay is generated using the lowest order QED matrix element squared:

$$ |A|^2 = \Gamma_{\gamma\gamma} 16\pi^3 M^4 \frac{\alpha}{\pi q^2} \left( 1 - \frac{q^2}{M^2} \right)^2 \times \left( 1 + \cos^2 \theta^* + \frac{4m_e^2}{q^2} \sin^2 \theta^* \right) |F(q^2)|^2 $$

where $\theta^*$ is the angle of $e^+$ in the dilepton rest frame with respect to the dilepton momentum in the overall $\pi^0$ decay system, $M$ and $m_e$ are $\pi^0$ and $e^\pm$ masses respectively, $\Gamma_{\gamma\gamma}$ is the partial $\pi^0 \rightarrow \gamma\gamma$ decay width, and $F(q^2)$ (with $q^2$ the squared momentum transfer of the off-shell photon) is the $\pi^0$ transition form factor. The form factor close to $q^2 = 0$ is parametrized as: $F(q^2) = 1 + a q^2 / M^2$. The value of the dimensionless linear coefficient $a$ is $0.032 \pm 0.004$ [42].

The matrix element from Eq. (4) leads to the following unperturbed $d\Gamma/dq$ distribution [43] for the standard lowest order electromagnetic decay $\pi^0 \rightarrow e^+e^-\gamma$ of Fig. 1a:

$$ \frac{d\Gamma}{dq} = \frac{4\alpha}{3\pi} \frac{1}{q^2} \left[ 1 + \frac{4m_e^2}{q^2} \right] \left[ 1 + \frac{2m_e^2}{q^2} \right] \times \left( 1 - \frac{q^2}{M^2} \right)^3 |F(q^2)|^2. $$

3. Data analysis

The first stage of data analysis is to extract a clean signal of $\pi^0 \rightarrow e^+e^-\gamma$ decays. The results shown in the previous section suggest that in $pp$ interactions at 550 MeV electron–positron pairs come nearly exclusively from the $\pi^0$ meson decays. Therefore, in order to maximize the yield of the $\pi^0 \rightarrow e^+e^-\gamma$ events we use an inclusive data sample requesting events with (i) at least one proton identified in the FD, (ii) an $e^+e^-$ pair identified in the CD. There is no request of an additional photon cluster and we have included events from both triggers corresponding to phase space regions (1) and (2). The distribution of the reconstructed invariant mass of the electron–positron pair, $q = IM(e^+e^-)$, is shown in Fig. 3a. This spectrum is well described by the sum of $\pi^0 \rightarrow e^+e^-\gamma$ and $\pi^0 \rightarrow \gamma\gamma$ (with photon conversion). The data sample contains $1.8 \times 10^8$ reconstructed events.

The $\pi^0 \rightarrow \gamma\gamma$ events are efficiently removed by a condition on the reconstructed position of the $e^+e^-$ vertex. Fig. 4 shows the distance ($R$) of the reconstructed vertex from the COSY beam axis. The contributions of the $\pi^0 \rightarrow \gamma\gamma$ and $\pi^0 \rightarrow e^+e^-\gamma$ decays, simulated according to the known branching ratios, are in

![Fig. 3](image-url)

**Fig. 3.** The reconstructed $e^+e^-$ invariant mass $q = IM(e^+e^-)$: a) before and b) after the cuts for reducing the conversion background. The experimental data are denoted by black points. Results of simulations for $\pi^0 \rightarrow \gamma\gamma$ (blue line) and $\pi^0 \rightarrow e^+e^-\gamma$ (green line) decays are normalized according to the known branching ratios. The normalization of random coincidences (dotted line) was fitted in order to reproduce the $IM(e^+e^-) > 150$ MeV range. The sum of all simulated contributions is given by the red line. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this Letter.)

![Fig. 4](image-url)

**Fig. 4.** Distribution of the distance $R$ between the COSY beam axis and the reconstructed point of closest approach of $e^+$ and $e^-$ tracks: experimental data (black crosses); simulations for $\pi^0 \rightarrow \gamma\gamma$ (blue line), the $\pi^0 \rightarrow e^+e^-\gamma$ decay (green line), and the sum of the two contributions (red line). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this Letter.)
very good agreement with the observed distribution and they are well separated. In order to further reduce the external conversion background one uses the invariant mass of the $e^+e^-$ calculated from the momentum directions at the points where the tracks intersect the beam tube, $IM_b$, shown in Fig. 5. The selection cut is performed in the $IM_b$ vs. $R$ plane (Fig. 5). The cut removes 98% of the $\pi^0 \rightarrow \gamma\gamma$ events which contribute to $IM(e^+e^-)$ distribution due to conversion.

The finally reconstructed $dN/dq$ distribution, containing nearly $5 \times 10^5$ entries, is shown in Fig. 3b. It is well described by the simulations of the $\pi^0 \rightarrow e^+e^-\gamma$ decay channel alone with a very small (approx. 3000 events) admixture of background from the $\pi^0 \rightarrow \gamma\gamma$ decay. The data in this work represent the world largest data sample of $\pi^0 \rightarrow e^+e^-\gamma$ events, which is almost an order of magnitude larger than the sample used for the previously published results from the SINDRUM experiment [37,44].

3.1. Upper limit for the BR($\pi^0 \rightarrow \gamma(U \rightarrow e^+e^-)$)

A distinctive feature of the expected signal of the decay $\pi^0 \rightarrow \gamma(U \rightarrow e^+e^-)$ (Fig. 1b) is the appearance of a narrow peak (the width being given by the detector resolution) in the invariant mass distribution of the electron–positron pair at the $U$ boson mass. The electrodynamics process $\pi^0 \rightarrow \gamma\gamma \rightarrow e^+e^-\gamma$ (Fig. 1a) both represents the irreducible background and is used for normalization. Due to the expected small decay width of the $U$ boson, the interference term is negligible and the signal from the $U$ boson can be tested by constructing an incoherent sum of the two contributions.

The experimental data are described well by the simulation based on Eq. (4) alone as shown in Fig. 3. The difference between reconstructed experimental $q$ distribution and the sum of all simulated contributions is given in Fig. 6. The errors include both statistical uncertainties of the data sample as well as the systematic ones due to the simulation of the detector response. In addition there are superimposed five example distributions corresponding to the $\pi^0 \rightarrow U\gamma \rightarrow e^+e^-\gamma$ process for $U$ boson masses of 30, 50, 70 and 90 MeV and $BR(\pi^0 \rightarrow U\gamma) = 10^{-4}$ (the corresponding $\epsilon$ values are: 0.0077, 0.0088, 0.0113, and 0.0169 respectively).

![Fig. 6](image-url)

**Fig. 5.** Correlation between $R$ and $IM_b$ variables for the experimental data. The selection cut is shown by the diagonal line. The events below the line mainly come from photon conversions in the beam pipe.

**Fig. 6.** Difference between the reconstructed $e^+e^-$ invariant mass distribution and the sum of all simulated contributions (black points). The resolution and sensitivity for a hypothetical decay $U \rightarrow e^+e^-$ are illustrated by the superimposed red histograms. They represent the signals expected for the $\pi^0 \rightarrow U\gamma \rightarrow e^+e^-\gamma$ process with $U$ boson masses of $M_U = 30, 50, 70$ and 90 MeV and $BR(\pi^0 \rightarrow U\gamma) = 10^{-4}$ (the corresponding $\epsilon$ values are: 0.0077, 0.0088, 0.0113, and 0.0169 respectively).

Fig. 7. A 90% CL upper limit (smoothed) for the $BR(\pi^0 \to \gamma U)$ from this Letter (solid line) compared to the result of the SINDRUM experiment [37] (dotted line).

Fig. 8. Summary of the 90% CL upper limits for the mixing parameter $\epsilon^2$ from WASA-at-COSY (red solid line) compared to SINDRUM $\pi^0 \to e^+e^-$ [37] (dotted line) and recent combined KLOE $\phi \to \gamma e^+e^-$ [47] (dashed dotted line). The authors thank technical staff at Forschungszentrum Jülich for support in preparation of and during the experiment.

The branching ratio of $\pi^0 \to \gamma U$ is related to $\epsilon^2$ by [46,21]:

$$\Gamma(\pi^0 \to \gamma U)/\Gamma(\pi^0 \to \gamma \gamma) = 2\epsilon^2 |F(M_U^2)|^2 \left(1 - M_U^2/M^2\right)^3.$$  (8)

The resulting upper limits for the $\epsilon^2$ parameter is shown in Fig. 8 and compared with other experiments.

The recent limits for the electron $g = 2$ are taken from recent QED calculations Refs. [33,32] and a measurement of alpha in atomic physics [48]. Our upper limit improves the recent combined KLOE limits [47] at low $M_U$. We use a disparate experimental setup and different meson decay as source of $e^+e^-$ pairs. Together the data significantly reduce the parameter space for mass and mixing strength of a hypothetical dark photon $U$, if the latter is assumed to account for the presently seen deviation between the Standard Model prediction and the experimental value of the muon anomalous magnetic moment. The experiment presented in the Letter if repeated with an order of magnitude larger statistics would cover the remaining part of this region of interest. The collected data can also be used to determine the $\pi^0$ transition form factor.
