Lower bounds for randomized and quantum query complexity using Kolmogorov arguments

Sophie Laplante∗ Frédéric Magniez∗

Abstract

We prove a very general lower bound technique for quantum and randomized query complexity, that is easy to prove as well as to apply. To achieve this, we introduce the use of Kolmogorov complexity to query complexity. Our technique generalizes the weighted, unweighted methods of Ambainis, and the spectral method of Barnum, Saks and Szegedy. As an immediate consequence of our main theorem, adversary methods can only prove lower bounds for boolean functions \( f \) in \( O(\min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)})\)), where \( C_0, C_1 \) is the certificate complexity, and \( n \) is the size of the input. We also derive a general form of the ad hoc weighted method used by Høyer, Neerbek and Shi to give a quantum lower bound on ordered search and sorting.

1 Introduction

1.1 Overview

In this paper, we study lower bounds for randomized and quantum query complexity. In the query model, the input is accessed using oracle queries, and the query complexity of an algorithm is the number of calls to the oracle. Since it is difficult to obtain lower bounds on time directly, the query model is often used to prove concrete lower bounds, in classical as well as quantum computation.

The two main tools for proving lower bounds of randomized query complexity, the polynomial method \([BBC+01]\) and the adversary method \([Amb02]\), were successfully extended to quantum computation. In the randomized setting, the adversary method is most often applied using Yao’s minimax principle \([Yao77]\). Using a different approach, which introduces the notion of quantum adversaries, Ambainis developed a general scheme in which it suffices to analyze the combinatorial properties of the function in order to obtain a quantum lower bound. Recently, Aaronson \([Aar03]\) brought these combinatorial properties back to randomized computation, using Yao’s minimax principle.

The most general method for proving lower bounds in quantum query complexity is the semidefinite programming method of Barnum, Saks and Szegedy \([BSS03]\). This method is in fact an exact characterization of the query complexity. However, the method is so general as to be very difficult to apply to obtain concrete lower bounds. Barnum, Saks and Szegedy gave a weaker method derived from the semidefinite programming approach, using weight matrices and their largest eigenvalue. This spectral method can be thought of as a generalization of Ambainis’ unweighted method. Other
generalizations of Ambainis’ unweighted method have been previously introduced \cite{BS02,Amb03}. All of them use a weight function on the instances. The difficulty in applying these methods is finding a good weight function on the instances. Høyer, Neerbek and Shi \cite{HNS02} were the first to use such weight assignments to prove lower bounds for searching in ordered lists and sorting. Their \textit{ad hoc} method, though similar in many respects, does not fall into setting of the weighted method of Ambainis \cite{Amb03}.

This paper presents a new, very general adversary technique (Theorem 1) to prove lower bounds in quantum and randomized query complexity. We believed that this technique is simpler to prove and to apply. It is based on the framework of Kolmogorov complexity. This framework has proven to be very useful for proving negative results in other models of computation, for example for number of rounds and length of advice in random-self-reductions in \cite{FFLN98,BL99}. The techniques we use here are an adaptation of those techniques to the framework of query complexity. We expect that this framework will not only prove to be useful for negative results in other quantum models of computation, for instance, communication complexity, but also for finer analysis of query complexity in terms of the number of rounds of queries.

The proof of Theorem 1 is in two parts. The first part (Divergence Lemma) shows how fast the computations can diverge when they start on different inputs. This part depends on the model of computation (randomized or quantum). The quantum case of this lemma was first proven by Ambainis \cite{Amb02}. The second part (Query Information Lemma) does not depend on the model of computation. It establishes the relationship between the Kolmogorov complexity of individual positions of the input, and the probability that a given algorithm makes a query to this position. Whereas Aaronson \cite{Aar03} used a different approach to prove a version of Ambainis’ method for randomized algorithms, here we use the same framework to establish lower bounds for both quantum and randomized query complexities (QQC and RQC).

We show that our method encompasses all previous adversary methods, including the quantum and randomized weighted methods \cite{Amb03,Aar03} (Theorem 2) and the spectral method \cite{BSS03} (Theorem 3). As an immediate consequence of our main theorem (observed by Troy Lee), our method can only prove lower bounds for boolean functions in $O(\min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)})$, where $C_0$ and $C_1$ is the certificate complexity of negative and positive instances, respectively, of $f$, and $n$ is the size of the input (Theorem 4). Prior to our work, it was known \cite{Amb03} that the unweighted Ambainis method \cite{Amb02} Theorem 5.1] could not prove bounds better than $\Omega(\sqrt{C_0(f) C_1(f)})$; Szegedy \cite{Sze03} also proved independently that the semidefinite programming method could not prove lower bounds better than $O(\min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)})$, and Zhang \cite{Zha03} proved the same thing for Ambainis’ weighted method.

We also give a generalization (Theorem 5) of the \textit{ad hoc} proofs of Høyer, Neerbek and Shi \cite{HNS02} as a corollary of our method. For this we introduce a new distance scheme. This new scheme separates the quantum part from the combinatorial part of these \textit{ad hoc} proofs. Using it, we prove the lower bound of \cite{HNS02} using only combinatorial arguments. We end the paper by giving some applications of our method to prove lower bounds for some graph properties: bipartiteness (Theorem 6) and connectivity (Theorem 7). This lower bounds were proven in \cite{DHH+03}. We reprove them here to illustrate the simplicity of our method.
1.2 Main result

Our main result is stated below.

**Theorem 1.** There exists a constant $C > 0$ such that the following holds. Let $\Sigma$ be a finite set, let $n \geq 1$ be an integer, and let $S \subseteq \Sigma^n$ and $S'$ be sets. Let $f : S \to S'$. Let $A$ be an algorithm that for all $x \in S$ computes $f$, with bounded error $\varepsilon$ and at most $T$ queries to the input. Then for every $x, y \in S$ with $f(x) \neq f(y)$:

1. If $A$ is a quantum algorithm then
   \[ T \geq C \times \frac{1 - 2\varepsilon(1 - \varepsilon)}{\sum_{i : x_i \neq y_i} \sqrt{2^{-K(i|x,A) - K(i|y,A)}}}; \]

2. If $A$ is a randomized algorithm then
   \[ T \geq C \times \frac{1 - 2\varepsilon}{\sum_{i : x_i \neq y_i} \min\left(2^{-K(i|x,A)}, 2^{-K(i|y,A)}\right)}. \]

We briefly describe the intuition behind the proof of Theorem 1. Consider an algorithm that purports to compute $f$, presented with two inputs $x, y$ that lead to different outputs. The algorithm must query those positions where $x$ and $y$ differ with average probability of the order of $\frac{1}{T}$, or it will not successfully compute the function. On the other hand, the queries that are made with high average probability can be described succinctly given the input and the algorithm, using the Shannon-Fano code. If we exhibit a pair of strings $x, y$ for which there is no succinct description of any of the positions where $x$ and $y$ differ, then the number of queries must be large.

The same reasoning can be applied to classical and to quantum computing; the only difference is how fast two different input states cause the outputs to diverge to different outcomes.

To conclude the introduction we give a very simple application, for Grover search.

**Example 1.** Fix $n$ and a quantum algorithm $A$ for Grover search for instances of length $n$. Let $z$ be a binary string of length $\log n$, with $K(z|A) \geq \log n$. Let $j$ be the integer between 0 and $n - 1$ whose binary expansion is $z$. Consider $x$, the all 0's string, and let $y$ be everywhere 0 except at position $i = j + 1$, where it is 1. Then $K(i|x,A) \geq \log n - O(1)$ and $K(i|y,A) = O(1)$, therefore, $\text{QQC}($Search$) = \Omega(\sqrt{n})$.

2 Preliminaries

2.1 Kolmogorov complexity

We use a few standard results in Kolmogorov complexity and information theory in this paper. We briefly review these here. The reader is invited to consult standard textbooks such as [LV97] for more background on Kolmogorov complexity, and [CT91] for more on information theory. We denote the length of a finite string $x$ by $|x|$. We assume that the Turing machine’s alphabet is the same finite alphabet as the alphabet used to encode instances of the function under consideration. Letters $x, y$ typically represent instances; $i$ is an index into the representation of the instance; and $p, q$ are probability distributions. Programs are denoted $P$, and the output of a Turing machine $M$ on input $x$ is written $M(x)$. When there are multiple inputs, we assume that a standard encoding of tuples is used.
Definition 1. Let \( M \) be a Turing machine. Let \( x \) and \( y \) be finite strings.

1. The Kolmogorov complexity of \( x \) given \( y \) with respect to \( M \) is denoted \( C_M(x|y) \), and defined as follows:
\[
C_M(x|y) = \min(|P| \text{ such that } M(P, y) = x).
\]

2. A set of strings is prefix-free if no string is a prefix of another in the set.

3. The prefix-free Kolmogorov complexity of \( x \) given \( y \) with respect to \( M \) is denoted \( K_M(x|y) \), and defined as follows:
\[
K_M(x|y) = \min(|P| \text{ such that } M(P, y) = x),
\]
where \( P \) is taken in some fixed prefix-free set.

In the rest of the paper \( M \) is some fixed universal Turing machine, and we will write \( C \) and \( K \) instead of \( C_M \) and \( K_M \). When \( y \) is the empty string, we write \( K(x) \) instead of \( K(x|y) \).

Proposition 1. There exists a constant \( c \geq 0 \) such that for every finite string \( \sigma \),
\[
K(x|\sigma) \leq K(x) + c, \text{ and } K(x) \leq K(\sigma) + K(x|\sigma) + c.
\]

Proposition 2 (Kraft’s inequality). Let \( S \) be any prefix-free set of finite strings. Then
\[
\sum_{x \in S} 2^{-|x|} \leq 1.
\]

Proposition 3 (Shannon’s coding theorem). Consider a source \( S \) of finite strings where \( x \) occurs with probability \( p(x) \). Then for any code for \( S \), the average code length is bounded below by the entropy of the source, that is, if \( x \) is encoded by the code word \( c(x) \) of length \( |c(x)| \),
\[
H(S) = \sum_{x:p(x)\neq 0} p(x) \log(\frac{1}{p(x)}) \leq \sum_{x:p(x)\neq 0} p(x)|c(x)|.
\]

Lemma 1. Let \( S \) be a source as above. Then for any fixed finite string \( \sigma \), there exists a string \( x \) such that \( p(x) \neq 0 \) and \( K(x|\sigma) \geq \log(\frac{1}{p(x)}) \).

Proof. By Shannon’s coding theorem,
\[
H(S) = \sum_{x:p(x)\neq 0} p(x) \log(\frac{1}{p(x)}) \leq \sum_{x:p(x)\neq 0} p(x)K(x|\sigma),
\]
because \( K(x|\sigma) \) is the length of an encoding of \( x \). Therefore there exists \( x \) such that \( p(x) \neq 0 \) and \( K(x) \geq \log(\frac{1}{p(x)}) \).

The Shannon-Fano code is a prefix-free code that encodes each word \( x \) with \( p(x) \neq 0 \), using \( \lceil \log(\frac{1}{p(x)}) \rceil \) bits. We will write \( \log(\frac{1}{p(x)}) \) to simplify notation. The code can easily be computed given a description of the probability distribution. This allows us to write the following proposition, where \( K(x|S) \) means the prefix-free Kolmogorov complexity of \( x \) given a finite description of \( S \).

Proposition 4 (Shannon-Fano code). There exists a constant \( c \geq 0 \), such that for every source \( S \) as above, for all \( x \) such that \( p(x) \neq 0 \),
\[
K(x|S) \leq \log(\frac{1}{p(x)}) + c.
\]
We shall also use the following bound on conditional Kolmogorov complexity.

**Proposition 5.** There is a constant \( c \geq 0 \) such that for any three strings \( x, y, z \),

\[
K(z|x) \geq K(x, y) - K(y|z, x) + K(z|x, y, K(x, y)) - c.
\]

**Proof.** Using [LV97, Theorem 3.9.1, page 232], there is a constant \( c_1 \geq 0 \) such that

\[
|K(a, b) - K(a) - K(b|a, K(a))| \leq c_1.
\]

Substituting \( x, y \) for \( a \) and \( z \) for \( b \):

\[
K(x, y) + K(z|x, y, K(x, y)) - c_1 \leq K(x, y, z) \leq K(x) + K(z|x) + K(y|z, x) + c_2,
\]

which gives the result.

## 2.2 Randomized and quantum query models

The quantum query model was implicitly introduced by Deutsch, Jozsa, Simon and Grover [Deu85, DJ92, Sim97, Gro96], and explicitly by Beals, Buhrman, Cleve, Mosca and de Wolf [BBC+01]. In this model, as in its classical counterpart, we pay for accessing the oracle, but unlike the classical case, the machine can use the power of quantum parallelism to make queries in superposition. Access to the input \( x \in \Sigma^n \), where \( \Sigma \) is a finite set, is achieved by way of a query operator \( O_x \). The query complexity of an algorithm is the number of calls to \( O_x \).

The state of a computation is represented by a register \( R \) composed of three subregisters: the query register \( i \in \{0, \ldots, n\} \), the answer register \( z \in \Sigma \) and the work register \( w \). We denote a register using the ket notation \( |R\rangle = |i\rangle|z\rangle|w\rangle \), or simply \( |i, z, w\rangle \). In the quantum (resp. randomized) setting, the state of the computation is a complex (resp. non-negative real) combination of all possible values of the registers. Let \( H \) denote the corresponding finite-dimensional vector space. We denote the state of the computation by a vector \( |\psi\rangle \in H \) over the basis \( (|i, z, w\rangle)_{i,z,w} \). Furthermore, the state vectors are unit length for the \( \ell_2 \) norm in the quantum setting, and for the \( \ell_1 \) norm in the randomized setting.

A \( T \)-query algorithm \( A \) is specified by a \((T+1)\)-uple \((U_0, U_1, \ldots, U_T)\) of matrices. When \( A \) is quantum (resp., randomized), the matrices \( U_i \) are unitary (resp., stochastic). The computation takes place as follows. The query operator is the unitary (resp. stochastic) matrix \( O_x \) that satisfies \( O_x|i, z, w\rangle = |i, z \oplus x_i, w\rangle \), for every \( i, z, w \), where by convention \( x_0 = 0 \). Initially the state is set to some fixed value \( |0, 0, 0\rangle \). Then the sequence of transformations \( U_0, O_x, U_1, O_x, \ldots, U_{T-1}, O_x, U_T \) is applied.

We say that the algorithm \( A \varepsilon\)-computes a function \( f : S \to S' \), for some sets \( S \subseteq \Sigma^n \) and \( S' \), if the observation of the last bits of the work register equals \( f(x) \) with probability at least \( 1 - \varepsilon \), for every \( x \in S \). Then \( QC(f) \) (resp. \( RQC(f) \)) is the minimum query complexity of quantum (resp. randomized) query algorithms that \( \varepsilon_0\)-compute \( f \), where \( \varepsilon_0 \) is a fixed positive constant no greater than \( \frac{1}{3} \).

### 3 Proof of the main theorem

This section is devoted to the proof of the main theorem. We prove Theorem \( \Box \) in two main steps. Lemma\( \Box \) shows how fast the computations diverge when they start on different individual
inputs, in terms of the query probabilities. This lemma depends on the model of computation. Lemma 3 establishes the relationship between the Kolmogorov complexity of individual positions of the input, and the probability that a given algorithm makes a query to this position. This lemma is independent of the model of computation. Theorem 1 follows immediately by combining these two lemmas.

In the following two lemmas, let $A$ be an $\epsilon$-bounded error algorithm for $f$ that makes at most $T$ queries to the input. Let $p^x_t(i)$ be the probability that $A$ queries $x_i$ at query $t$ on input $x$, and let $\mathbb{P}^x(i) = \frac{1}{T} \sum_{t=1}^{T} p^x_t(i)$ be the average query probability over all the time steps up to time $T$. We assume henceforth without loss of generality that $p^x(i) > 0$. (For example, we start by uniformly querying all positions and reverse the process.)

**Lemma 2 (Divergence Lemma).** For every input $x, y \in S$ such that $f(x) \neq f(y)$ the following holds.

1. For quantum algorithms:
   $$2T \sum_{i: x_i \neq y_i} \sqrt{\mathbb{P}^x(i) \mathbb{P}^y(i)} \geq 1 - 2\sqrt{\epsilon(1-\epsilon)}.$$

2. For randomized algorithms:
   $$2T \sum_{i: x_i \neq y_i} \min(\mathbb{P}^x(i), \mathbb{P}^y(i)) \geq 1 - 2\epsilon.$$

We defer the proof of Lemma 2 to the end of this section.

The next lemma relates the query probabilities to the Kolmogorov complexity of the strings. In this lemma and the results that follow, we assume that a finite description of the algorithm is given. Using the knowledge of $A$, we may assume without loss of generality that the function $f$ that it computes is also given, as is the length $n$ of the inputs. With additional care, the additive constants in all of the proofs can be made very small by adding to the auxiliary information made available to the description algorithms, those constant-size programs that are described within the proofs.

**Lemma 3 (Query Information Lemma).** There exists an absolute constant $c \geq 0$ such that for every input $x \in S$ and position $i \in \{1, \ldots, n\}$,

$$K(i|x, A) \leq \log(\frac{1}{\mathbb{P}^x(i)}) + c.$$

**Proof.** We describe the program that prints $i$ given $x$ and $A$. Given $x$, use $A$ and $x$ to compute the probabilities $\mathbb{P}^x(i)$. This can be done in a finite number of steps because the number of queries is bounded by $T$. The program includes a hard coded copy of the encoding of $i$ under the Shannon-Fano code for this probability distribution. Decode this and print $i$. \hfill \square

From these two lemmas we derive the main theorem.

**Proof of Theorem 1** By Lemma 3 there is a constant $c \geq 0$ such that for any algorithm that makes at most $T$ queries, and any $x, y, i$,

$$\mathbb{P}^x(i) \leq 2^{-K(i|x, A)+c} \quad \text{and} \quad \mathbb{P}^y(i) \leq 2^{-K(i|y, A)+c}.$$

This is true in particular for all those $i$ where $x_i \neq y_i$. Combining this with Lemma 2 concludes the proof of the main theorem with $C = 2^{-c-1}$. \hfill \square
We now give the proof of Lemma 2. The proof of the quantum case is very similar to the proofs found in many papers which give quantum lower bounds on query complexity. To our knowledge, the randomized case is new despite the simplicity of its proof. Whereas Aaronson [Aar03] used a different approach to prove a version of Ambainis’ method for randomized algorithms, our lemma allows us to use the same framework to establish lower bounds for both quantum and randomized query complexities.

**Proof of Lemma 2.** Let $|\psi_t^x\rangle$ be the state of the $\epsilon$-bounded error algorithm $A$ just before the $t$th oracle query, on input $x$. By convention, $|\psi_T^y\rangle$ is the final state. When $A$ is a quantum algorithm $|\psi_t^x\rangle$ is a unit vector for the $\ell_2$-norm; otherwise it is a probabilistic distribution, that is, a non-negative and unit vector for the $\ell_1$-norm. Observe that the $\ell_1$-distance is the total variation distance.

First we prove the quantum case. Initially, the starting state of $A$ does not depend on the input, thus before the first question we have $|\psi_1^x\rangle = |\psi_1^y\rangle$, so $\langle \psi_1^x | \psi_1^y \rangle = 1$. At the end of the computation, if the algorithm is correct with probability $\epsilon$, then $|\langle \psi_T^x | \psi_T^y \rangle| \leq 2\sqrt{\epsilon(1-\epsilon)}$. At each time step, we consider how much the two states can diverge.

**Claim 1.** $|\langle \psi_T^x | \psi_T^y \rangle - \langle \psi_T^x | \psi_T^y \rangle| \leq 2 \sum_{t=1}^{T} \sum_{i:x_i \neq y_i} \sqrt{p_t^x(i)p_t^y(i)}$.

The proof of Claim 1 can be found in Appendix A

Over $T$ time steps, the two states diverge as follows. The proof uses only Claim 1 and the Cauchy-Schwartz inequality.

$$1 - 2\sqrt{\epsilon(1-\epsilon)} \leq |\langle \psi_T^x | \psi_T^y \rangle - \langle \psi_T^x | \psi_T^y \rangle|$$

$$\leq \sum_{t=1}^{T} |\langle \psi_t^x | \psi_t^y \rangle - \langle \psi_t^x | \psi_t^y \rangle| \leq \sum_{t=1}^{T} 2 \sum_{i:x_i \neq y_i} \sqrt{p_t^x(i)p_t^y(i)}$$

Now we prove the randomized case. Again, initially $|\psi_1^x\rangle = |\psi_1^y\rangle$. At the end of the computation, if the algorithm is correct with probability $\epsilon$, then $\| |\psi_T^x\rangle - |\psi_T^y\rangle \|_1 \geq 1 - 2\epsilon$. At each time step, the distribution states now diverge according the following claim.

**Claim 2.** $\| \psi_{t+1}^x - \psi_{t+1}^y \|_1 \leq \| \psi_T^x - \psi_T^y \|_1 + 2 \sum_{t=1}^{T} \min \{p_t^x(i), p_t^y(i)\}$.

The proof of Claim 2 can be found in Appendix A

We now conclude the proof.

$$1 - 2\epsilon \leq \sum_{t=1}^{T} \| |\psi_{t+1}^x| - |\psi_{t+1}^y| \|_1 - \| \psi_T^x - \psi_T^y \|_1$$

$$\leq \sum_{t=1}^{T} 2 \sum_{i:x_i \neq y_i} \min \{p_t^x(i), p_t^y(i)\} \leq 2T \sum_{i:x_i \neq y_i} \min \{p_t^x(i), p_t^y(i)\}.$$
4 Comparison with previous adversary methods

In this section, we reprove, as a corollary of Theorem 1, the previously known adversary lower bounds. Our framework also allows us to obtain somewhat stronger statements for free.

To obtain the previously known adversary methods as a corollary of Theorem 1, we must give a lower bound on terms $K(i|x, A)$ and $K(i|y, A)$. To this end, we apply Proposition 5 and give a lower bound on $K(x, y)$, and upper bounds on $K(x|i, y)$ and $K(y|i, x)$. The lower bound is obtained by applying Lemma 1, a consequence of Shannon’s coding theorem, for an appropriate distribution. The upper bounds are obtained using the Shannon-Fano code, for appropriate distributions.

The following lemma is the general formulation of the sketch above.

**Lemma 4.** There exists a constant $C > 0$ such that the following holds. Let $\Sigma$ be a finite set, let $n \geq 1$ be an integer, and let $S \subseteq \Sigma^n$. Let $q$ be a probability distribution on $S^2$, let $p$ be a probability distribution on $S$ and let $\{p'_{x,i} : x \in S, 1 \leq i \leq n\}$ be a set of probability distributions on $S$. Then for every finite string $\sigma$, there exist $x, y \in S$ with $q(x, y) \neq 0$, such that

$$\frac{1}{\sum_{i: x_i \neq y_i} \sqrt{2^{-K(i|x, \sigma) - K(i|y, \sigma)}}} \geq C \times \min_{i: x_i \neq y_i} \left( \frac{\sqrt{p(x)p'_{x,i}(y) - K(y)p'y_{i,x}(x)}}{q(x, y)} \right),$$

and

$$\frac{1}{\sum_{i: x_i \neq y_i} \min \left( 2^{-K(i|x, \sigma)}, 2^{-K(i|y, \sigma)} \right)} \geq C \times \min_{i: x_i \neq y_i} \left( \frac{p(x)p'_{x,i}(y) - K(y)p'y_{i,x}(x)}{q(x, y)} \right),$$

provided that $q(x, y) = 0$ whenever $p(x) = 0$ or $p(y) = 0$, or $p'_{x,i}(x) = 0$ or $p'_{y,i}(y) = 0$ for some $i$ such that $x_i \neq y_i$.

**Proof.** In this proof, $c_1, \ldots, c_5$ are some appropriate nonnegative constants. By Lemma 1 there exists a pair $(x, y)$ such that $q(x, y) \neq 0$ and

$$K(x, y|\sigma, p, p') \geq \log \left( \frac{1}{q(x, y)} \right),$$

where $p'$ stands for a complete description of all the $p'_{x,i}$.

Fix $x$ and $y$ so that this holds. By using the Shannon-Fano code (Proposition 3),

$$K(x|p) \leq \log \left( \frac{1}{p(x)} \right) + c_1 \quad \text{and} \quad K(y|x, i, p'_x, i) \leq \log \left( \frac{1}{p'_{x,i}(y)} \right) + c_1,$$

for any $i$ such that $x_i \neq y_i$. By Proposition 5,

\[
K(i|x, \sigma) \geq K(i|x, \sigma, p, p') - c_3 \\
\geq K(x, y|\sigma, p, p') - K(x|p) - K(y|i, x, p'_{x,i}) + K(i|y, x, K(x, y), \sigma, p, p') - c_4 \\
\geq \log \left( \frac{1}{q(x, y)} \right) - \log \left( \frac{1}{p(x)} \right) - \log \left( \frac{1}{p'_{x,i}(y)} \right) + K(i|y, x, K(x, y), \sigma, p, p') - c_5 \\
= \log \left( \frac{p(x)p'_{x,i}(y)}{q(x, y)} \right) + K(i|y, x, K(x, y), \sigma, p, p') - c_5.
\]

Similarly,

$$K(i|y, \sigma) \geq \log \left( \frac{p(y)p'_{y,i}(x)}{q(x, y)} \right) + K(i|x, y, K(x, y), \sigma, p, p') - c_5$$

This concludes the proof of the lemma using Kraft’s inequality (Proposition 2) and letting $C = 2^{-c_5}$. \qed
4.1 Ambainis’ weighted scheme

**Theorem 2 (Ambainis’ weighted method).** Let $\Sigma$ be a finite set, let $n \geq 1$ be an integer, and let $S \subseteq \Sigma^n$ and $S'$ be sets. Let $f : S \rightarrow S'$. Consider a weight scheme as follows:

- Every pair $(x, y) \in S^2$ is assigned a non-negative weight $w(x, y)$ such that $w(x, y) = 0$ whenever $f(x) = f(y)$.
- Every triple $(x, y, i)$ is assigned a non-negative weight $w'(x, y, i)$ such that $w'(x, y, i) = 0$ whenever $x_i = y_i$ or $f(x) = f(y)$.

For all $x, i$, let $s \subseteq l, l'$ be sets. Let $S$ be the restriction of $R$ to pairs $x, y$ whenever $x_i = y_i$.

The relation in Ambainis’ original statement is implicit in this formulation, since it corresponds to the non-zero-weight pairs. A weaker version of the randomized case was proven independently by Aaronson [Aar03] using a completely different approach. We show that Theorem 2 follows from Theorem 1.

Proof. We derive probability distributions $q, p, p'$ from the weight schemes as follows. Let $W = \sum_{x, y} w(x, y)$ in

$$q(x, y) = \frac{w(x, y)}{W}, \quad p(x) = \frac{wt(x)}{W}, \quad \text{and} \quad p'(y, x, i) = \frac{w'(y, x, i)}{v(x, i)}.$$

It is easy to check that by construction and hypothesis, these distributions satisfy the conditions of Lemma 4. Rearranging and simplifying the terms allows us to conclude. □

We conclude this section by sketching the proof of the unweighted version of Ambainis’ adversary method, as it affords a simpler combinatorial proof, that does not require Lemma 4. To simplify notation we omit additive constants and the usual auxiliary strings including $A$.

Let $R \subseteq S \times S$, be a relation on pairs of instances, where $(x, y) \in R \Rightarrow f(x) \neq f(y)$, and let $R_i$ be the restriction of $R$ to pairs $x, y$ for which $x_i = y_i$. Viewing the relation $R$ as a bipartite graph, let $l, l', m, m'$ be as follows.

- $m$ is a lower bound on the degree of all $x \in X$,
- $m'$ is a lower bound on the degree of all $y \in Y$,
- for any fixed $x$ and $i, 1 \leq i \leq n$, the number of $y$ adjacent to $x$ for which $x_i = y_i$ is at most $l$,
- for any fixed $y$ and $i, 1 \leq j \leq n$, the number of $x$ adjacent to $y$ for which $x_i = y_i$ is at most $l'$. 

9
We make the following observations.

1. \(|R| \geq \max\{m|X|, m'|Y|\}\), so \(\exists x, y \ K(x, y) \geq \max (\log(m|X|), \log(m'|Y|))\).

2. \(\forall x \in X, K(x) \leq \log(|X|)\) and \(K(y) \leq \log(|Y|)\), for all \(y \in Y\).

3. \(\forall x, y, i \text{ with } (x, y) \in R, K(y|i, x) \leq \log(l)\) and similarly, \(K(x|i, y) \leq \log(l')\).

For any \(i \text{ with } x_i \neq y_i\), by Proposition 5,

\[
K(i|x) \geq K(x, y) - K(x) - K(y|i, x) + K(i|x, y, K(x, y)) \geq \log(m|X|) - \log(|X|) - \log(l) + K(i|x, y, K(x, y)) = \log(m'l') + K(i|x, y, K(x, y)).
\]

The same proof works to show that \(K(i|y) \geq \log(m'l') + K(i|x, y, K(x, y))\). By Theorem 1 and Kraft’s inequality,

\[
\QC(f) = \Omega\left(\sqrt{\frac{mm'}{ll'}}\right).
\]

4.2 Spectral lower bound

We now show how to prove the spectral lower bound of Barnum, Saks ans Szegedy \cite{bss03} as a corollary of Theorem 1. Recall that for any matrix \(\Gamma\), \(\lambda(\Gamma)\) is the largest eigenvalue of \(\Gamma\).

**Theorem 3 (Barnum-Saks-Szegedy spectral method).** Let \(\Sigma\) be a finite set, let \(n \geq 1\) be an integer, and let \(S \subseteq \Sigma^n\) and \(S'\) be sets. Let \(f : S \rightarrow S'\). Let \(\Gamma\) be an arbitrary \(S \times S\) nonnegative real symmetric matrix that satisfies \(\Gamma(x, y) = 0\) whenever \(f(x) = f(y)\). For \(i = 1, \ldots, n\) let \(\Gamma_i\) be the matrix:

\[
\Gamma_i(x, y) = \begin{cases} 0, & \text{if } x_i = y_i; \\ \Gamma(x, y), & \text{otherwise}. \end{cases}
\]

Then

\[
\QC(f) = \Omega\left(\frac{\lambda(\Gamma)}{\max_i \lambda(\Gamma_i)}\right).
\]

**Proof.** Let \(|\alpha\) (resp. \(|\alpha_i\)) be the unit eigenvector of \(\Gamma\) (resp. \(\Gamma_i\)) with nonnegative entries and whose eigenvalue is \(\lambda(\Gamma)\) (resp. \(\lambda(\Gamma_i)\)). We define the probability distributions \(q, p, p'\) as follows. Let \(W = \sum_{x,y} w(x, y)\) in

\[
q(x, y) = \frac{\Gamma(x, y)|x\alpha\rangle\langle y\alpha|}{|\alpha\rangle|\Gamma\alpha\rangle}, \quad p(x) = |x\alpha|^2, \quad p'_i(x, y) = \frac{\Gamma_i(x, y)|y\alpha_i\rangle}{|x\alpha_i\rangle}, \quad \text{for any } x, y, i.
\]

By construction these distributions satisfy the conditions of Lemma 4 which suffices to conclude.
5 Certificate complexity and adversary techniques

Let \( f \) be a boolean function. For any positive instance \( x \in \Sigma^n \) of \( f(x)=1 \), a positive certificate for \( f(x) \) is the smallest subset of indices \( I \subseteq [n] \) of \( x \), such that for any \( y \) with \( x_i = y_i \) for all \( i \in I \), \( f(y)=1 \).

The 1-certificate complexity of \( f \), denoted \( C_1(f) \), is the size of the largest positive certificate for \( f(x) \), over all positive instances \( x \). The 0-certificate complexity is defined similarly for negative instances \( x \) of \( f(x)=0 \).

Prior to our work, it was known that the best possible bound that could be proven using the unweighted adversary technique \cite{Amb02} is \( O(\sqrt{nC_0(f)C_1(f)}) \). Independently, Szegedy \cite{Sze03} showed that the best possible lower bound using the spectral method is \( O(\min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)})) \), and Zhang \cite{Zha03} proved the same for Ambainis’ weighted method.

The following lemma, due to Troy Lee, results in a very simple proof of the fact that our method, and hence, all the known variants of the adversary method, cannot prove lower bounds larger than \( \min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)}) \).

**Lemma 5.** There exists a constant \( c \geq 0 \) such that the following holds. Let \( \Sigma \) be a finite set, let \( n \geq 1 \) be an integer, and let \( S \subseteq \Sigma^n \) be a set. Let \( f : S \to \{0, 1\} \). For every \( x, y \in S \) with \( f(x) = 0 \) and \( f(y) = 1 \), there is an \( i \) with \( x_i \neq y_i \) for which \( K(i|x, f) \leq \log(C_0(f)) + c \), and similarly, there is a \( j \) with \( x_j \neq y_j \) such that \( K(j|y, f) \leq \log(C_1(f)) + c \).

**Proof.** Let \( I \) be the lexicographically smallest certificate for \( f(x) \). Since \( f(x) \neq f(y) \), and \( x \) and \( y \) must differ on some \( i \in I \). To describe \( i \) given \( x \), it suffices to give an index into \( I \), which requires \( \log(C_0(f)) + c \) bits. The same can also be done with \( x \) and \( y \) reversed. \( \square \)

**Theorem 4.** Let \( \Sigma \) be a finite set, let \( n \geq 1 \) be an integer, and let \( S \subseteq \Sigma^n \) be a set. Let \( f : S \to \{0, 1\} \). Then any quantum query lower bound for \( f \) given by Theorem 3 is in \( O(\min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)})) \).

**Proof.** Let \( A \) be a quantum algorithm that computes \( f \) with bounded error by making at most \( T \) queries to the input. Since a description of \( f \) can be obtained from a description of \( A, K(i|x, A) \leq K(i|x, f) + O(1) \). Therefore, the lower bound given by Theorem 3 is \( O\left(\frac{1}{\sum_{i: x_i \neq y_i} \sqrt{2^{-K(i|x, f) - K(i|y, f)}}}\right) \), where \( f(x) \neq f(y) \). This is \( O(\min(\sqrt{nC_0(f)}, \sqrt{nC_1(f)})) \) by Lemma 5. \( \square \)

6 Applications

6.1 A general method for distance schemes

We generalize the technique of Høyer, Neerbek and Shi \cite{HNS02}, which they used to prove lower bounds on ordered search and sorting. Though their technique is similar, it does not appear to be a special case of the weighted adversary method.

Here, we restrict ourselves to those weight functions that take values of the form \( \frac{1}{d} \), for integer values \( d \). Therefore, instead of a weight function, we consider an integer function \( D \), which may be thought of as a distance function on pairs of instances (even though it is not the case in general).

We will define the load of an instance \( x \), to be the maximum number of instances \( y \) at distance \( d \) from \( x \), for any \( d \). This will allow us to bound the complexity of printing \( y \), given \( x \) and \( d \). (In the case of ordered search, the load will be 1 for all instances.)
More formally, for any non-negative integer function \( D \) on pairs \((x, y)\), we define the right load \( \text{RL}(x, i) \) to be the maximum over all values \( d \), of the number of \( y \) such that \( D(x, y) = d \) and \( x_i \neq y_i \). The left load \( \text{LL}(y, i) \) is defined similarly, inverting \( x \) and \( y \).

**Theorem 5.** Let \( \Sigma \) be a finite set, let \( n \geq 1 \) be an integer, and let \( S \subseteq \Sigma^n \) and \( S' \) be sets. Let \( f : S \rightarrow S' \). Let \( D \) be a non-negative integer function on \( S^2 \) such that \( D(x, y) = 0 \) whenever \( f(x) = f(y) \). Let \( W = \sum_{x,y:D(x,y)\neq0} \frac{1}{D(x,y)} \). Then

\[
\text{QQC}(f) = \Omega \left( \frac{W}{|S|} \min_{x,y:D(x,y)\neq0,x_i=y_i} \left( \frac{1}{\sqrt{\text{RL}(x,i)\text{LL}(y,i)}} \right) \right),
\]

\[
\text{RQC}(f) = \Omega \left( \frac{W}{|S|} \min_{x,y:D(x,y)\neq0,x_i=y_i} \left( \max \left( \frac{1}{\text{RL}(x,i)}, \frac{1}{\text{LL}(y,i)} \right) \right) \right).
\]

**Proof.** We use a variation on Lemma \[4\]. We define probability distributions \( q(x, y) = \frac{1}{D(x,y)\times W} \) whenever \( D(x, y) \neq 0 \) and \( q(x, y) = 0 \) otherwise; \( p(x) = \frac{1}{|S|} \). Fix \( \sigma \) to be the string containing a description of \( A \) and \( D \), where \( D \) is a complete description of the distance function, and where we assume that \( A \) includes a description of \( f \), hence \( \text{RL}(x,i), \text{LL}(y,i) \) and are also given.

We give an upper bound on the terms \( K(y|x,i) \) and \( K(x|y,i) \) directly, using left and right loads. Given \( x, i \) and some integer \( d > 0 \), there are at most \( \text{RL}(x,i) \) instances \( y \) such that \( D(x,y) = d \) and \( x_i \neq y_i \). Therefore

\[
K(y|x,i,\sigma) \leq \log(D(x,y)) + \log(\text{RL}(x,i)) + c,
\]

where \( c \geq 0 \) is some constant, The same is true for \( K(x|y,i) \):

\[
K(y|x,i,\sigma) \leq \log(D(x,y)) + \log(\text{LL}(y,i)) + c.
\]

Now, we conclude following the same sketch as the proof of Lemma \[4\].

We reprove some of the lower bounds of Høyer, Neerbek and Shi. The distance schemes we use are exactly the ones of \[HNS02\]. Whereas they did not separate the quantum part from the combinatorial part in their proofs, here we only need to evaluate the combinatorial objects \( \text{RL} \) and \( \text{LL} \) to get the results.

**Corollary 1.** \( \text{QQC(Ordered search)}, \text{RQC(Ordered search)} = \Omega(\log n) \).

**Proof.** Fix \( \Sigma = \{0,1\} \). We only consider the set of instances \( S \) of length \( n \) of the form \( 0^{a-1}1^{n-a} \). Note that \( |S| = n \). Define distance for pairs \((x, y)\) in \( S^2 \) as \( D(x,y) = b - a \), and \( D(x,y) = 0 \) for all other instances, where \( x = 0^{a-1}1^{n-a} \) and \( y = 0^b1^{n-b} \) with \( 1 \leq a < b \leq n \). The inverse distance has total weight \( W = \Theta(n \log n) \). Furthermore, for every \( x, y, i \) such that \( D(x,y) \neq 0 \) and \( x_i \neq y_i \), \( \text{RL}(x,i) = \text{LL}(y,i) = 1 \). The result follows by Theorem \[5\].

A lower bound for sorting \[HNS02\] in the comparison model can also be obtained by applying Theorem \[5\].

**Corollary 2.** \( \text{QQC(Sorting)}, \text{RQC(Sorting)} = \Omega(n \log n) \).
Proof. Fix $\Sigma = \{0,1\}$. An input is an $n \times n$ comparison matrix $M_\sigma$ defined by $(M_\sigma)_{i,j} = 1$ if $\sigma(i) < \sigma(j)$, and $(M_\sigma)_{i,j} = 0$ otherwise, where $\sigma$ is some permutation of $\{1,\ldots,n\}$. (In the usual array representation, the element of rank $r$ in the array would be stored at position $\sigma^{-1}(r)$.) The set $S$ of inputs is $\{M_\sigma : \sigma \in S_n\}$.

We consider pairs of instances $M_\sigma,M_{\sigma^{(k,d)}}$, where $\sigma^{(k,d)}$ is obtained from $\sigma$ by changing the value of the element of rank $k+d$ to a value that immediately precedes the element of rank $k$ in $\sigma$. This changes the rank of the $d$ elements of intermediate rank, incrementing their rank by one.

More formally, define $\sigma^{(k,d)} = (k,k+1,\ldots,k+d) \circ \sigma$, for $d \neq 0$. For every permutations $\sigma,\tau$ we let $D(M_\sigma,M_\tau) = d$ if there exists $k,d$ such that $\tau = \sigma^{(k,d)}$, and $D(M_\sigma,M_\tau) = 0$ otherwise. Observe that whenever $\tau = \sigma^{(k,d)}$, the comparison matrices $M_\sigma$ and $M_\tau$ differ only in entries $(\sigma^{-1}(k+d),\sigma^{-1}(i)) = (\tau^{-1}(k),\tau^{-1}(i+1))$ and $(\sigma^{-1}(i),\sigma^{-1}(k+d)) = (\tau^{-1}(i+1),\tau^{-1}(k))$, for $k \leq i \leq k+d-1$.

Then for every $\sigma,\tau,(i,j)$ such that $D(M_\sigma,M_\tau) \neq 0$ and $(M_\sigma)_{i,j} \neq (M_\tau)_{i,j}$, $RL(\sigma,(i,j)) = LL(\sigma,(i,j)) = 2$. This is because given $\sigma,i,j,d$, either $i = \sigma^{-1}(k+d)$ or $j = \sigma^{-1}(k+d)$, so there are two possible values for $(k,d)$. Similarly, $RL(\tau,(i,j)) = LL(\tau,(i,j)) = 2$. The inverse distance has total weight $W = \Theta((n!)n \log n)$ and the size of $S$ is $|S| = (n!)$. Applying Theorem 5 we conclude the proof. 

6.2 Graph properties

Theorem 6 ([DHH+03]). In the adjacency matrix model,

\[ QQC(\text{Bipartiteness}) = \Omega(n), \]

where $n$ is the number of vertices in the graph.

Proof. Let $G$ be the star on $n$ vertices. Let $i,j$ be two leaves of $G$ chosen such that $K(i,j|G) \geq \log \binom{n}{2}$. Define $H$ to be $G$ to which the single edge $(i,j)$ is added.

By hypothesis, $K(i,j|G) \geq \log \binom{n}{2}$. By Theorem 6 $QQC(\text{Bipartiteness}) = \Omega(n)$, as claimed.

6.2.2 Graph connectivity

Theorem 7 ([DHH+03]). In the adjacency matrix model,

\[ QQC(\text{GraphConnectivity}) = \Omega(n^{3/2}), \]

where $n$ is the number of vertices in the graph.
Proof. It suffices to consider one negative and one positive instance of graph connectivity, which we construct using the incompressibility method, using the ideas of [DHH+03]. Let $S$ be an incompressible string of length $\log(n - 1)! + \log \left( \frac{n}{2} \right)$, chopped into two pieces $S_1$ and $S_2$ of length $\log(n - 1)!$ and $\log \left( \frac{n}{2} \right)$, respectively. We think of $S_1$ as representing a hamilton cycle $C = (0, \pi(0) \cdots \pi(n-1), 0)$ through the $n$ vertices, and $S_2$ as representing a pair of distinct vertices $s, t$. Let $G$ contain the cycle $C$ and let $H$ be obtained from $G$ by breaking the cycle into two cycles at $s$ and $t$, that is, $H = G \setminus \{(\pi(s), \pi(s+1)), (\pi(t), \pi(t+1))\} \cup \{(\pi(s), \pi(t+1)), (\pi(s+1), \pi(t))\}$.

We show that for the four edges $e$ where $G$ and $H$ differ, $K(e|G) + K(e|H) \geq 3 \log n - 4$. Let $e_-, e'_-$ be the edges removed from $G$, and $e_+, e'_+$ be the edges added to $G$. Observe that up to an additive constant, $K(e_+|G) = K(e'_+|G)$ and $K(e_-|H) = K(e'_-|H)$. Let $e_-$ be one of the edges removed from $G$, w.l.o.g., $e_- = (\pi(s), \pi(s+1))$.

$$\log(n - 1)! + \log \left( \frac{n}{2} \right) \leq K(S) \leq K(G) + K(s|G) + K(t|G)$$

$$\leq K(G) + K(e_-|G) + \log n$$

$$K(e_-|G) \geq \log \left( \frac{n}{2} \right) - \log n = \log \frac{n-1}{2}$$
Assume w.l.o.g. that the smallest cycle of $H$ contains $\pi(s)$, and let $l$ be its length.

$$\log(n-1)! + \log\left(\frac{n}{2}\right) \leq K(S) \leq K(H) + K(e_-|H) + K(\pi(t), \pi(t+1)|H)$$

$$\leq \log\left(\frac{(n-1)!}{(n-l+1)!}\right) + \log(n-l-1)! + K(e_-|H) + \log l + \log(n-l)$$

$$K(e_-|H) \geq 2 \log n + \log(n-l) - \log(l) \geq 2 \log n.$$

For the added edges, $e_+, e'_+$, consider w.l.o.g. $e_+ = (\pi(s), \pi(t+1))$. Since $S$ is incompressible, $K(e_+|G) \geq K(s, t|G) \geq \log\left(\binom{n}{2}\right)$. Furthermore, $K(S) \leq K(H) + K(e_+|H) + K(e'_+|H)$, and $K(e'_+|H) \leq \log n$, so $K(e_+|H) \geq \log\left(\binom{n}{2}\right) - \log n = \log\frac{n-1}{2}$. The same proof shows that $K(e'_+|H) \geq \log\frac{n-1}{2}$.

7 Acknowledgements

We wish to thank Troy Lee, Christoph Dürr for many useful discussions, and Andris Ambainis for his helpful answers to our questions.

A Proofs of claims

Proof of Claim[1] Let

\[ |\psi^x_t\rangle = \sum_{i,z,w} \alpha_{i,z,w} |i, z, w\rangle, \quad \text{and} \quad |\psi^y_t\rangle = \sum_{i,z,w} \beta_{i,z,w} |i, z, w\rangle. \]

After the \( t \)th query is made, the states \( |\psi'^x_t\rangle = O_x|\psi^x_t\rangle \) and \( |\psi'^y_t\rangle = O_y|\psi^y_t\rangle \) are

\[ |\psi'^x_t\rangle = \sum_{i,z,w} \alpha_{i,z,w} |i, z \oplus x_i, w\rangle, \quad \text{and} \quad |\psi'^y_t\rangle = \sum_{i,z,w} \beta_{i,z,w} |i, z \oplus y_i, w\rangle. \]

Now, since the inner product is invariant under unitary transformations, we get

\[ \langle \psi'^x_{t+1} | \psi'^y_{t+1} \rangle = \langle \psi'^x_t | \psi'^y_t \rangle, \]
and therefore,

\[ |\langle \psi^x_t | \psi^y_{t+1} \rangle - \langle \psi^x_{t+1} | \psi^y_{t+1} \rangle| = | \sum_{i,z,w} \alpha_{i,z,w} \beta_{i,z,w} - \sum_{i,z,w} \alpha_{i,z,x_i,w} \beta_{i,z,y_i,w} | \]

\[ = | \sum_{i,z,w} \alpha_{i,z,w} \beta_{i,z,w} - \sum_{i,z,w} \alpha_{i,z,x_i,w} \beta_{i,z,y_i,w} | \]

\[ \leq \sum_{i:x_i \neq y_i} \left( \sum_{z,w} |\alpha_{i,z,w} \beta_{i,z,w}| + \sum_{z,w} |\alpha_{i,z,x_i,w} \beta_{i,z,y_i,w}| \right) \]

\[ \leq 2 \sum_{i:x_i \neq y_i} \sqrt{\left( \sum_{z,w} |\alpha_{i,z,w}|^2 \right) \left( \sum_{z,w} |\beta_{i,z,w}|^2 \right)} \]

\[ \leq 2 \sum_{i:x_i \neq y_i} \left( p^x_t(i)p^y_t(i) \right) \]

Proof of Claim: Let us write the distributions using the above formalism, that is,

\[ |\psi^x_t \rangle = \sum_{i,z,w} \alpha_{i,z,w} |i, z, w\rangle, \quad \text{and} \quad |\psi^y_t \rangle = \sum_{i,z,w} \beta_{i,z,w} |i, z, w\rangle. \]

Note that now, the vectors are unit for the \( \ell_1 \) norm. After the \( t \)th query is made, the states \( |\psi^x_{t+1} \rangle = O_x |\psi^x_t \rangle \) and \( |\psi^y_{t+1} \rangle = O_y |\psi^y_t \rangle \) are

\[ |\psi^x_{t+1} \rangle = \sum_{i,z,w} \alpha_{i,z,w} |i, z \oplus x_i, w\rangle, \quad \text{and} \quad |\psi^y_{t+1} \rangle = \sum_{i,z,w} \beta_{i,z,w} |i, z \oplus y_i, w\rangle. \]

Now, since the \( \ell_1 \) distance does not increase under stochastic matrices, we get

\[ \| |\psi^x_{t+1} \rangle - |\psi^y_{t+1} \rangle \|_1 \leq \| |\psi^x_t \rangle - |\psi^y_t \rangle \|_1, \]

and therefore,

\[ \| |\psi^x_{t+1} \rangle - |\psi^y_{t+1} \rangle \|_1 = \| \sum_{i,z,w} (\alpha_{i,z,w} |i, z \oplus x_i, w\rangle - \beta_{i,z,w} |i, z \oplus y_i, w\rangle) \|_1 \]

\[ = \sum_i \| \sum_{z,w} (\alpha_{i,z,w} |i, z \oplus x_i, w\rangle - \beta_{i,z,w} |i, z \oplus y_i, w\rangle) \|_1. \]

We now bound each term of the last sum separately. Fix any \( i \). If \( x_i = y_i \) then

\[ \| \sum_{z,w} (\alpha_{i,z,w} |i, z \oplus x_i, w\rangle - \beta_{i,z,w} |i, z \oplus y_i, w\rangle) \|_1 = \sum_{z,w} (\alpha_{i,z,w} |i, z, w\rangle - \beta_{i,z,w} |i, z, w\rangle) \|_1. \]
If \( x_i \neq y_i \) then,

\[
\| \sum_{z,w} (\alpha_{i,z,w} |i, z \oplus x_i, w\rangle - \beta_{i,z,w} |i, z \oplus y_i, w\rangle) \|_1 \\
\leq \| \sum_{z,w} (\alpha_{i,z,w} |i, z \oplus y_i, w\rangle - \beta_{i,z,w} |i, z \oplus y_i, w\rangle) \|_1 \\
+ \| \sum_{z,w} (\alpha_{i,z,w} |i, z \oplus x_i, w\rangle - \alpha_{i,z,w} |i, z \oplus y_i, w\rangle) \|_1 \\
\leq \| \sum_{z,w} (\alpha_{i,z,w} |i, z, w\rangle - \beta_{i,z,w} |i, z, w\rangle) \|_1 + 2 \| \sum_{z,w} \alpha_{i,z,w} |i, z, w\rangle \|_1 \\
= \| \sum_{z,w} (\alpha_{i,z,w} |i, z, w\rangle - \beta_{i,z,w} |i, z, w\rangle) \|_1 + 2p^x_t(i).
\]

In the same way we can prove that

\[
\| \sum_{z,w} (\alpha_{i,z,w} |i, z \oplus x_i, w\rangle - \beta_{i,z,w} |i, z \oplus y_i, w\rangle) \|_1 \\
\leq \| \sum_{z,w} (\alpha_{i,z,w} |i, z, w\rangle - \beta_{i,z,w} |i, z, w\rangle) \|_1 + 2p^y_t(i).
\]

We regroup these majorations and conclude

\[
\| |\psi^x_{t+1}\rangle - |\psi^y_{t+1}\rangle \|_1 \leq \sum_i \| \sum_{z,w} (\alpha_{i,z,w} |i, z, w\rangle - \beta_{i,z,w} |i, z, w\rangle) \|_1 + 2 \sum_{i:x_i \neq y_i} \min (p^x_t(i), p^y_t(i)) \\
= \| |\psi^x_t\rangle - |\psi^y_t\rangle \|_1 + 2 \sum_{i:x_i \neq y_i} \min (p^x_t(i), p^y_t(i)).
\]

\( \square \)
