ABSTRACT

Behavioural models are a valuable tool for software verification, testing, monitoring, publishing etc. However, they are rarely provided by the software developers and have to be extracted either from the source or from the compiled code. In the context of Java programs, a number of approaches exist for building behavioural models. Most of these approaches rely on the analysis of the compiled bytecode. Instead, we are looking to extract behavioural models—in the form of Finite State Machines (FSMs)—from the Java source code to ensure that the obtained FSMs can be easily understood by the software developers and, if necessary, updated or integrated into the original source code, e.g. in the form of annotations. Modern software systems are huge, rely on external libraries and interact with their environment. Hence, extracting useful behavioural models requires abstraction. In this paper, we present an initial approach to this problem by focusing on the extraction of FSMs modelling library APIs. We focus on the analysis of Java code involving the use of collections. To this end, we encode the operational semantics of collection operations using patterns of Boolean predicates. These patterns are instantiated based on the analysis of the source code of API implementation methods to form an encoding of the possible FSM transitions. A SAT solver is then used to determine the enabledness conditions (guards) of these transitions.

API, breaking changes, behavioral models, FSM, Java

1 INTRODUCTION

Behavioural models are a valuable tool for supporting the process of building the correct software, that could be beneficial during all phases of the development lifecycle: design and implementation [8, 26, 30], testing and verification [5, 12], coordination and monitoring [18, 25], deployment [7] etc.

One of the particular problem behavioral models could help to address is maintaining the API correctness. APIs provide a great way of scoping, encapsulating and presenting library functions [6]. Reusing components with the help of APIs helps to reduce the cost of software systems development and to increase their quality [9, 10, 17]. However, API development is not free of problems. When designed badly, API offers inefficient or even incorrect code requiring writing additional code to deal with it, which leads directly to the increased development cost [22]. When documented badly and without clear explanation of the correct sequence of method usage, API can demonstrate exceptional behaviours [3]. External APIs, being a black box, can contain error-prone dependencies and make systems prone to breaking changes that have to be addressed in the client code. A new version of an external interface evolving independently can break backward compatibility and may cause runtime failures of client systems. According to studies, breaking changes are being present in the significant amount of all new releases (70% [28], 75% [15], and 80% [16]). One can argue that building a dynamic model of libraries to help the developer understand the behaviour of methods operating on collections contradicts the fundamental principle of information hiding: a developer relying on knowledge of the API implementation would produce code even more prone to the breaking changes we want to address. We believe, however, that if a signature of an API method provides a developer with the insufficient information, she will need to make her assumptions in any case whether they are supported by the extracted model or not. But comparing the two models of different releases can show a developer if any breaking changes were introduced.

There exist various approaches based on behavioral models to deal with such problems possessing different levels of formality (from graphical representation [11] to employing behavioral types [2]) and ways of being produced and presented. In general, these models are expected to be expressive, rigorous, intuitive, well-structured and possess the adequate level of abstraction (be sufficiently detailed and precise) [21]. Such models could complement the code [29], be extracted from it [16, 27], from its binaries [28], from some intermediate representation or from other models [13, 14], from the execution traces [24] or be created to synthesize the code from them [21]. Our approaches follows the idea presented in [19, 23, 27]. Henzinger et al. have introduced the idea of safe and permissive interfaces (which allow all possible sequences of method calls not violating interface’s internal invariants and prohibits all others) and have presented an algorithm for automatically synthesizing them as a graph with nodes as predicates over interface’s internal states and labels as library calls. Godoy et al. were exploring search-based test generation techniques to exploit the abstraction of interfaces based on their enabledness (permitted sequence of method calls) in order to find possible failures. Parizk et al. were working on verification of java programs with a particular focus on collections. Their approach is based on using a predicate language and the idea of weakest preconditions to model the states and possible method calls of a collection interface and capture possible changes. The novelty of our approach concerning presented above lies in the presence and absence of guards that help to break the information into the one known (in this case this information goes to states) and the one unknown (which goes to guards and resolves dynamically). Another consequence of our
approach is that we can also achieve different levels of abstraction by adding more or fewer predicates and axioms.

We are interested in building behavioral models that have a tight connection with API implementation source code to provide feedback to developers on the behavior of the program. In this paper, we propose an approach to semi-automatic extraction of behavioral models for APIs written in Java in the form of Finite State Machines (FSMs), focusing on the code operating on collections.

The paper is structured as follows. In Section 2, we introduce a simple running example. In Section 3, we present our approach to model extraction. In Section 4, we discuss our assumptions and future work directions. Section 5 concludes the paper.

2 RUNNING EXAMPLE

Let’s imagine the API created for the users of a pharmaceutical company. In particular it allows users to create reservations for the set of medications and to manipulate this collections: add or remove elements. Each medication can have two identifiers where the second is the one provided by a third-party vendor. When a detail to be added or removed both ids are checked (see the code snippet below)

```
class ExampleImpl implements ExampleAPI {

    private Set<String> idSet;

    public ExampleImpl() {
        idSet = new HashSet<>();
    }

    public void add(String id) {
        idSet.add(id); // See Section 3.2 for the line numbers in the left margin
    }

    public void removeId(String idMain, String idOpt) {
        idSet.remove(idMain);
        if (idMain != idOpt) {
            idSet.remove(idOpt);
        } else {
        }
    }

}
```

During the last code review it was decided to migrate idSet collection from the HashSet to the TreeSet to present the order of the elements. However, this led to the unexpected exception, when some user tried to remove a medicine having only one id (remove("LK32EJ2", null)). This exception is not visible at the compilation but can be catched by the static code analysers, and it is clearly visible if we compare the behavioral models generated for the two versions of the code (see Figures 2 and 3).

These models show the result of calling the API methods add and remove. We model the states with the predicates we used to create this abstraction. The transitions are labeled with the API method names, some of them have the guards (values in square brackets) which are the conditions based on the methods variables evaluated dynamically, that have to be satisfied in order to fire the transition.

3 MODEL EXTRACTION APPROACH

3.1 Simplifying assumptions

We based our work on Java Collection Framework JDK 17—the most recent version at the time of writing [1]—and considered its General Purpose Implementations (GPI). We studied each GPI to capture its behaviour and to define its operational semantics taking into account differences in the implementation of methods for various interfaces. For the sake of brevity, we discuss only Set collections.

We focus on the contribution of collections to the object state. Thus, the defining property of sets, i.e. the absence of duplicates, is irrelevant. Other properties that can be taken into account are (1) the absence of duplicates, (2) whether the collection is ordered and (3) whether it permits null values. Here, we focus on the latter.

Furthermore, since the operation of enlarging the collection is called implicitly, we disregard the initial capacity and the load factor of the collection. Similarly, since element retrieval is not based on their position in the collection, we do not have to keep track of the insertion order. In particular, these assumptions allow us to process HashSet and LinkedHashSet in the same manner. For TreeSet, we have extra rules for adding and removing null elements.

In addition, we make the following assumptions that simplify the presentation. We summarise them here—further details are provided in Section 3.2. We will discuss the validity of these assumptions in Section 4. We assume that:

1. all conditions used in branching statements (if, while etc.) are Boolean expressions referring exclusively to comparisons of values and the contains() and isEmpty() operations on collections
2. the source code is formatted in such a manner that there is at most one operator per line, all branching statements have all their opening and closing braces and the closing braces are placed on separate lines from any other operators (cf. the example in Figure 1)
(3) there are only two types—collections and values—and any value can be stored in any collection
(4) all loops terminate.
We plan to gradually resolve these simplifications up to the limits of modern model checking and other static analysis techniques will permit.

3.2 Boolean encoding of method behaviour
Our approach relies on the predicate abstraction idea from [20]. For each method in the API under consideration, we proceed as follows.

Given a method, we consider a context comprising a set of collection symbols $C$ and a set of value symbols $V$. The symbols in $V$ can be literal constants (e.g. "null", "null1").

For two symbols $v_1, v_2 \in V$ (idem for $c_1, c_2 \in C$), we write $v_1 \equiv v_2$ if they are the same symbol; $v_1 = v_2$ denotes the predicate stating that their values are equal.

The definition of the context is a parameter of the approach, determining, in particular, the degree of refinement of the resulting model. Context values are used to form the following predicates:
- $\text{eq}_{v_1, v_2} \triangleq (v_1 = v_2)$ for $v_1, v_2 \in V$ ($v_1 \neq v_2$)
- $\text{eq}_{c_1, c_2} \triangleq (c_1 = c_2)$ for $c_1, c_2 \in C$ ($c_1 \neq c_2$)
- $\text{cnt}_{c, v}$ holds for $v \in V$ and $c \in C$ if $v$ is contained in $c$
- $\emptyset$ holds for $c \subseteq C$ if $c$ is empty
- $e$ holds if an exception has been thrown

We postulate the following axioms,
1. $\text{ax}_1(c, v_1, v_2) \triangleq (v_1, v_2) \in V$ ($v_1 \neq v_2$)
2. $\text{ax}_2(c_1, c_2, v) \triangleq (c_1 = c_2)$ for $c_1, c_2 \in C$ ($c_1 \neq c_2$)
3. $\text{ax}_3(c, v) \triangleq (\text{eq}(c, v))$

Let $P$ be the set of all the predicates above and $P' \triangleq \{p' \mid p \in P\}$. Assume that all operators of the method are numbered sequentially from 1 to $n$, with the numbering of branching operators corresponding to their closing braces (cf. Figure 1). For each predicate $p \in P$ and each $i \in [0, n]$, we define a Boolean variable $p^{i}$ corresponding to the valuation of $p$ after the execution of the operator $i$.

For a formula $\varphi \in \mathbb{B}[P, P']$, denote $\varphi^{i,j} \triangleq \varphi(P^{i}/P')$ the formula where each predicate $p$ (resp. $p'$) is substituted by the variable $p^{i}$ (resp. $p^{j}$). Similarly, $\varphi^{i} \triangleq \varphi(P^{i}/P)$ for $\varphi \in \mathbb{B}[P]$.

For a sequence of operators $s$ and two indices $i, j \in [0, n]$ ($i < j$), we define the encoding function $\text{enc}^{i,j}(s)$ as shown in Figure 4, where $s_{op}$ denotes the index of the last operator in a sequence $s$ and, in (4), $\varphi_{os}$ is the formula encoding the semantics of the operator $op$ (see Section 3.3 below). A method $\text{meth}$ with the body $s$ is then encoded by the formula

$$\text{enc}(\text{meth}) \triangleq \text{axioms}^{0} \land \text{enc}^{0,s_{op}}(s),$$

with the formula $\text{axioms}$ defined by (5).

3.3 Predicate semantics of operators
The predicate semantics of an operator $op$ is given by a quadruple $(C_{op}, V_{op}, P_{op}, f_{op})$, where
- $(C_{op}, V_{op})$ is a context, comprising the sets $C_{op}$ and $V_{op}$ of, respectively, collection and value variables

$$\text{enc}^{i,j}(op; s) \triangleq \text{enc}^{i,op_{1}}(op) \land \text{enc}^{op_{2},j}(s) \quad (1)$$

$$\text{enc}^{i,j}(\text{while}(e) s) \triangleq \neg \text{cnt}_{i} \quad (2)$$

$$(\text{if}(e) s_1 \text{else } s_1) \triangleq \text{enc}^{i,\text{cnt}_{i}}(s_1) \land \text{enc}^{i,\text{cnt}_{i}+1}(s_2) \land \neg \text{cnt}_{i} \implies \bigwedge_{p \in P} p^{i} = p^{i+1} \land \neg \text{cnt}_{i} \implies \bigwedge_{p \in P} p^{i} = p^{i+1} \quad (3)$$

$$\text{enc}^{i,j}(op) \triangleq \varphi_{op}^{i,j} \land \text{axioms}^{i} \quad (4)$$

$$(\bigwedge_{c \in C} \text{eq}(c, v_1, v_2) \land \bigwedge_{v \in V} \text{cnt}(c, v) \land \bigwedge_{c \in C} \text{eq}(c, v_1, v_2) \land \bigwedge_{v \in V} \text{cnt}(c, v) \quad (5)$$

Figure 4: Definition of the encoding function $\text{enc}^{i,j}(\cdot)$

- $P_{op}$ is a subset of predicates as in Section 3.2 indexed by the variables from $C_{op}$ and $V_{op}$
- $f_{op} \in \mathbb{B}[P_{op}, P'_{op}]$ is a Boolean formula on these predicates and $\mathbb{B}[P_{op}, P'_{op}]$ is Boolean algebra generated by $P_{op} \cup P'$ (set of Boolean formulas with variables from $P$ and $P'$)

Intuitively, $P_{op}$ is the set of predicates that must hold for the values may be affected by the operator.

For example, consider the method $\text{m.add}(v)$ of a HashSet $c$. Its predicate semantics is given by the formula

$$f_{c, \text{add}(v)} \triangleq \text{cnt}_{c,v} \land \neg \text{empty}_{c,v} \quad (6)$$

Here, $c_{\text{add}(v)} = \{c\}$, $V_{\text{add}(v)} = \{v\}$, $P_{\text{add}(v)} = \{\text{cnt}_{c,v}, \text{empty}_{c,v}\}$.

Let us consider, as another example, the method $\text{m.clear}()$ of a collection $c$. Its predicate semantics is given by the formula

$$f_{c, \text{clear}()} \triangleq \text{empty}_{c} \quad (7)$$

Despite $c$ not appearing in $f_{c, \text{clear}()}$, we take the same $c_{\text{clear}()} = \{c\}$, $V_{c, \text{clear}()} = \{c\}$ and $P_{\text{clear}()} = \{\text{cnt}_{c,v}, \text{empty}_{c}\}$ as above.

Indeed, the value of the $\text{cnt}_{c,v}$ predicate, for all value symbols in the context, may be modified by this method, even though $ax3$ means that this does not have to be specified explicitly in $f_{c, \text{clear}()}$.

For each operator invocation in the source code, some of the variables in $C_{op}$ and $V_{op}$ will be positionally matched with the symbols in the context ($C, V$). E.g., for an invocation $\text{idSet} \text{clear}()$, $c \in C_{\text{clear}()}$ is matched to $\text{idSet} \in C$ but $v \in V_{\text{clear}()}$ is not matched to any symbol in $V$. For the sake of clarity, let us abuse the notation as follows: we denote $C_{op} \setminus C$ (resp. $V_{op} \setminus V$) the set of variables that are not matched positionally.

The formula $\varphi_{op}$ encoding the operator $op$ (see (4) in Figure 4) is then defined as follows:

$$\varphi_{op} \triangleq \bigwedge_{P_{free} \subseteq P} \bigwedge_{v \in V_{op} \setminus V} P_{op}[\mu, v],$$

with $P_{free} \subseteq P$
where \( f_{\text{op}}[\mu, v] \) denotes the formula obtained by substituting each unmatched variable \( c \in C_{\text{op}} \setminus C \) (resp. \( v \in V_{\text{op}} \setminus V \)) by the symbol \( \mu(c) \) (resp. \( v(z) \)) and similarly for \( P_{\text{op}}[\mu, v] \).

Intuitively, the first conjunct in (6) means that the formula \( f_{\text{op}} \) is instantiated for all possible values of the unmatched variables. The second conjunct means that all predicates in \( P \) that do not appear in the semantics of \( op \) maintain their previous values.

Notice, finally, that a predicate \( p' \), with \( p \in P_{\text{op}} \), that is not fully constrained by \( f_{\text{op}} \) might take any value, representing the absence of the corresponding information. For instance, consider the method \( c.\text{remove}(v) \) of a HashSet \( c \). Its predicate semantics is given by the formula

\[
\mathcal{f}_{c.\text{remove}(v)} \overset{\text{def}}{=} \neg\text{cnt}_{c, a} \land (\text{empty}_c \implies \text{empty}'_c),
\]

with, again, \( C_{c.\text{remove}(v)} = \{c\}, V_{c.\text{remove}(v)} = \{v\} \) and \( P_{c.\text{remove}(v)} = \{\text{cnt}_{c, a}, \text{empty}_c\} \). If \( c \) is not empty before the call to \( c.\text{remove}(v) \) it may or may not become empty after the call, depending on whether \( v \) is the only value contained therein.

### 3.4 Computing the FSM

Given a context \((C, V)\) with the corresponding set of predicates \( P \) as defined in Section 3.2, we observe that the symbols can be partitioned into \textit{state} and \textit{indeterminacy} symbols: \( C = C_{\text{st}} \uplus C_\text{nd} \) and \( V = V_{\text{st}} \uplus V_{\text{nd}} \), such that \( C_{\text{st}} \) and \( V_{\text{st}} \) contain constants and class fields, whereas \( C_\text{nd} \) and \( V_{\text{nd}} \) contain method parameters, un-evaluated functions etc. This induces several partitions on the set of predicates: \( P = P_{\text{st}} \uplus P_\text{nd} \), such that \( P_{\text{st}} \) is a subset of predicates that refer only to symbols in \( C_{\text{st}} \) and \( V_{\text{st}} \).

A \textit{state} is a partial valuation \( \sigma : P_{\text{st}} \rightarrow B \). A concrete state is a total valuation \( \sigma : P_{\text{st}} \rightarrow \mathbb{B} \). We say that one state \( \sigma_1 \) refines another \( \sigma_2 \), denoted \( \sigma_1 < \sigma_2 \) if \( \text{dom}(\sigma_2) \subseteq \text{dom}(\sigma_1) \) and \( \sigma_1(p) = \sigma_2(p) \), for all \( p \in \text{dom}(\sigma_2) \). We say that a set of states \( \Sigma \) is \textit{complete} if every state refines some state of \( \Sigma \), i.e. for every \( \sigma : P_{\text{st}} \rightarrow \mathbb{B} \), there exists \( \sigma' \in \Sigma \), such that \( \sigma < \sigma' \). Notice that any complete set of states must comprise the empty valuation \( \sigma_0 \), having \( \text{dom}(\sigma_0) = \emptyset \). Clearly, for any given implementation of an API, there can be different complete sets of states. In particular, the set \( \{\sigma_0\} \) is complete. So is the set of all concrete states \( \{\sigma : \text{dom}(\sigma) = P_{\text{st}} \} \cup \{\sigma_0\} \).

Given a context \((C, V)\), a set of predicates \( P \) and a complete set of states \( \Sigma \), we build a non-deterministic FSM \((\Sigma, \sigma_0, A \rightarrow)\), where \( \sigma_0 \) is the initial state, \( A \) is the set of methods provided by the API under consideration and \( \rightarrow \subseteq \Sigma \times A \times \mathbb{B} \times \Sigma = \text{the transition relation} \), where the third component is the transition guard.

To compute the transition relation \( \rightarrow \), we proceed as follows. For each method \( \text{meth} \in A \) and each pair of states \( \sigma_1, \sigma_2 \in \Sigma \), we define

\[
\varphi_{\text{meth}}[\mu, v] \overset{\text{def}}{=} \bigwedge_{p \in \text{dom}(\sigma_1)} (p^0 = \sigma_1(p)) \land \text{enc}(\text{meth}) \land \bigwedge_{p \in \text{dom}(\sigma_2)} (p^{\text{meth}} = \sigma_2(p))
\]

(see Section 3.2) and submit it to a SAT solver. If \( \varphi_0 \) is satisfiable we obtain a model \( m_1 : \{p^i | p \in P, i \in \{0, \text{meth}\} \} \rightarrow \mathbb{B} \). We define

\[
\varphi_1 \overset{\text{def}}{=} \varphi_0 \land \neg \bigwedge_{i=0}^{\text{meth}_1} \bigwedge_{p \in P} (p^i = m_1(p^i))
\]

and submit it to the SAT solver again, repeating until we obtain some \( \varphi_n \) that is unsatisfiable. The transition is then

\[
\sigma_1 \xrightarrow{\text{meth}[g]} \sigma_2, \quad \text{with } g = \bigwedge_{i=1}^n \bigwedge_{p \in P_{\text{nd}}} (p = m_i(p^0)).
\]

Notice that, if \( \varphi_0 \) is unsatisfiable, we have \( g = \text{false} \).

Applying this approach to the example in Figure 1 we obtain the FSMs in Figures 2 and 3. We do so using the set of all concrete states, in which each state is a combination of predicates from \( P \) (predicates forming the states could be selected to tune the level of the model’s abstraction, e.g. in our example we rely on the \text{empty}_c \) predicate even though \( P \) is not limited by it. The common context for the HashSet version of the example is \((\{\text{idSet}\}, \emptyset)\). For methods add and removeId we take the union with, respectively, \((\emptyset, \{\text{id}\})\) and \((\emptyset, \{\text{idMain}, \text{idOpt}\})\). The predicates are the same as in Section 3.2, with \( P_{\text{st}} = \{\text{empty}, \text{isEmpty}\} \) (we exclude \( c \), since it appears neither in the axioms nor in the semantics of the operators involved).

For the TreeSet version, we add \text{null} to the common context and \( e \) to \( P_{\text{st}} \) since they appear in the semantics of the operators, e.g.

\[
\mathcal{f}_{e.\text{add}(v)} \overset{\text{def}}{=} (eq_{\text{null}} = eq_{\text{null}}'_{\text{e, add}}) \land \neg eq_{\text{null}} \implies \text{(cnt}_{e, c} \land \neg \text{empty}_c \land (e' = e))
\]

\[
\mathcal{f}_{e.\text{remove}(v)} \overset{\text{def}}{=} (eq_{\text{null}} = eq_{\text{null}}'_{\text{e, remove}}) \land \neg eq_{\text{null}} \implies \text{(cnt}_{e, c} \land (\text{empty}_c \implies \text{empty}'_c \land e') \land (e' = e))
\]

The full Z3 encodings of the two versions can be found in [4].

### 4 DISCUSSION & FUTURE WORK

The model extraction approach proposed above is based on ideas that are well-known in the Formal Methods community. The novelty lies in their application for the extraction of behavioural models from Java source code. More importantly, our main goal is not to use these models for verification but rather for assisting software engineers in the development process, making API more usable due to the provision of additional information on the expected order of the calls of the operation, and, eventually, for model-based monitoring and coordination. This allows us, in particular, to aim for a less restrictive behavioural model, namely non-deterministic FSMs with guards. This change of perspective also makes the semi-automatic approach more acceptable: indeed, we believe that it is much easier to get developers to help refining an existing model than to provide one from scratch. Both limitations and the advantages of the approach refer to the problem of building the model with the right level of abstraction. Abstraction excessively leads to primitive models, useless in a practical context. Abstraction insufficiently leads to undecidability and the state explosion problem. We leave implementation of abstraction-tuning possibility as a future work.

The semi-automatic nature of our approach arises from several levels of parameterisation among which the key one is choosing the appropriate predicates for the specification of the semantics of the basic operations. To some extent, this remark addresses the simplifying assumption (1) in Section 3.1, which can be substantially
We propose an approach to the extraction of behavioural models in which we consider beyond the near-future scope of this work. Trees and Control Flow Graphs to explore the source code and variable is aliasing the other one, we can force the corresponding it is parametrised by the choice of important symbols, predicates the form of non-deterministic FSMs with guards from Java imple-

5 CONCLUSION

and states. This makes it highly flexible and allows the integration of expert knowledge from developers. The presented approach is fully formalised. Although the underlying ideas are well known in the Formal Methods community, we believe that their combined application for the extraction of FSMs with guards is novel and can be applied to the benefit of the Software Engineering community. We are planning to develop a tool based on the proposed approach and use it in our future projects for the purposes of monitoring and coordination of software components.
