PDF in PDFs from Hadronc Tensor and LaMET

Keh-Fei Liu

Department of Physics and Astronomy, University of Kentucky, Lexington, KY 40506

Abstract

We point out a problem of the phenomenological definition of the valence partons as the difference between the partons and antipartons in the context of the NNLO evolution equations. After demonstrating that the classification of the parton degrees of freedom (PDF) of the parton distribution functions (PDFs) are the same in the path-intergral formulations of the hadronic tensor and the quasi-PDF with LaMET, we resolve the problem by showing that the proper definition of the valence should be in terms of those in the connected insertions only. We also prove that the strange partons appear as the disconnected sea in the nucleon.

1 Introduction

Partonic structure of the nucleon has been discovered and extensively studied in deep inelastic scattering (DIS) of leptons. Further experiments in Drell-Yan process, semi-inclusive DIS (SIDIS) help to identify and clarify the flavor dependence, particularly the sea partons [1]. The first experimental evidence that the sea patrons have non-trivial flavor dependence is revealed in the experimental demonstration of the violation of Gottfried sum rule. The original Gottfried sum rule,

\[ I_G \equiv \int_0^1 dx \left( F_p^2(x) - F_n^2(x) \right) / x = 1/3, \]

was obtained under the assumption that \( \bar{u} = \bar{d} \) sea partons are the same [2]. However, the NMC measurement [3] of 

\[ \int_0^1 dx \left( F_p^2(x) - F_n^2(x) \right) / x \]

turns out to be \( 0.235 \pm 0.026, a 4 \sigma \) difference from the Gottfried sum rule, which implies that the \( \bar{u} = \bar{d} \) assumption was invalid. Other flavor-dependent issues under active experimental and theoretical pursuits include the intrinsic strange and charm partons [4], and the \( s(x) - \bar{s}(x) \) [5, 6] and \( c(x) - \bar{c}(x) \) [7] asymmetries.

In this work, we shall scrutinize the definition of the valence parton in the context of \( s(x) - \bar{s}(x) \) asymmetry and the NNLO evolution. The conventional phenomenological definition of the valence parton is \( q^-(x) \equiv q(x) - \bar{q}(x) \). Given this definition, one faces the following questions:

1. It has been suggested that the ‘NuTeV anomaly’ [8] might be resolved if there is an \( s(x) - \bar{s} \) asymmetry [5, 6]. Even though the global analyses do not have a definite conclusion yet, when NNLO is considered for parton evolution, there is a term in the splitting function which will generate \( s(x) - \bar{s} \) asymmetry. This involves a quark loop with three gluon lines attached to it. It is small, i.e. \( O(\alpha_s^3) \), but non-zero nonetheless. Hence the question: although there is no net strangeness in the nucleon (i.e. \( \int dx (s(x) - \bar{s}) = 0 \)), why should the strange parton with \( s^-(x) = s(x) - \bar{s}(x) \neq 0 \) be a part of the valence distribution. This is contrary to the picture of the quark model, particularly
its $SU(6)$ classification of the hadrons, in which the nucleon is composed of $u$ and $d$ valence quarks only, while the strange is part of the sea.

2. Similarly, there is a question about the NNLO evolution. One of the NNLO equations for $q^- (x)$ [9, 10, 11] is

$$\frac{dq^\mu_i}{dt} = (P^\mu_{qq} - P^\mu_{q\bar{q}}) \otimes q_i^- + (P^s_{qq} - P^s_{q\bar{q}}) \otimes \Sigma_v,$$

where $t = \ln \mu^2$. $P^\mu_{qq}$, $P^s_{qq}$, and $P^s_{q\bar{q}}$ are splitting functions, and

$$\Sigma_v \equiv \sum_i (q_i - \bar{q}_i); \quad q_i^- \equiv q_i - \bar{q}_i.$$

When and if $q_i^-$ is interpreted as the valence distribution, the second term on the right of Eq. (1) implies that the valence distributions of $d$ and $s$ can affect the evolution of the valence $u$ parton. This appears to be contradictory to the fact that there is no flavor-changing couplings in QCQ between the valence quarks.

These concerns are hints that something is wrong with identifying $q^-$ as the valence distribution. It turns out these puzzles can be resolved via the Euclidean path-integral formulation of QCD.

This manuscript is organized as follows. Sec. 2 gives the path-integral formulation of the hadronic tensor which defines the parton degrees of freedom. Sec. 3 gives the quasi-parton approach to calculating the PDF directly on the lattice via large momentum effective theory (LaMET). It is shown that the parton degrees of the freedom are identical to those from the hadronic tensor. We shall present the resolution of the above puzzles in Sec. 4. Finally, we prove in Sec. 5 that the strange quarks only appear in the disconnected insertions in nucleon matrix elements. The summary is given in Sec. 6.

## 2 Euclidean Path-integral Formulation of the Hadronic Tensor

The Euclidean hadronic tensor was formulated in the path-integral formalism to identify the origin of the Gottfried sum rule violation [12]. It is the current-current correlator in the nucleon and can be obtained by the following four-point-to-two-point correlator ratio

$$\tilde{W}_{\mu\nu}(\vec{q}, \vec{p}, \tau) = \frac{E_p}{m_N} \frac{\text{Tr}(\Gamma_{eG_{pp}}(t_0, t_1, t_2, t_f))}{\text{Tr}(\Gamma_{eG_{pp}}(t_0, t_f))} \bigg|_{t_f - t_2 \gg 1/\Delta E_p, t_1 - t_0 \gg 1/\Delta E_p}$$

$$= \langle N(\vec{p})| \int d^3x \frac{e^{i\vec{q}\cdot\vec{x}}}{4\pi} e^{-i\vec{q}\cdot\vec{p}} J_{\mu}(\vec{x}, \tau) J_{\nu}(0, 0)|N(\vec{p}) \rangle, \quad (3)$$

where $\tau = t_2 - t_1$ is the Euclidean time separation between the current $J_{\nu}(t_2)$ and $J_{\mu}(t_1)$. The current-source and sink-current separations $t_1 - t_0$ and $t_f - t_2$ are much larger than
the inverse of the energy $\Delta E_p$ between the nucleon and its first excited state, so that the nucleon excited states are filtered out at large time separations. Formally, the inverse Laplace transform converts $\tilde{W}_{\mu\nu}(\vec{q}, \vec{p}, \tau)$ to the Minkowski hadronic tensor

$$W_{\mu\nu}(\vec{q}, \vec{p}, \nu) = \frac{1}{2m_N} \int_{c-i\infty}^{c+i\infty} d\tau e^{\nu \tau} \tilde{W}_{\mu\nu}(\vec{q}, \vec{p}, \tau),$$

(4)

with $c > 0$. This is basically doing the anti-Wick rotation to go back to the Minkowski space. In practice with the lattice calculation, it is not possible to perform the inverse Laplace transform in Eq. (4), as there is no data on the imaginary $\tau$. Instead, one can turn this into an inverse problem and find a solution from the Laplace transform [15]

$$\tilde{W}_{\mu\nu}(\vec{q}, \vec{p}, \tau) = \int d\nu e^{-\nu \tau} W_{\mu\nu}(\vec{q}, \vec{p}, \nu).$$

(5)

This has been studied [16, 17] with the inverse algorithms such as Backus-Gilbert, Maximum Entropy and Bayesian Reconstruction methods. The expected spectral density of the neutrino-nucleon scattering cross section or structure functions is illustrated in Fig. 1 which shows that there are several kinematic regions in the spectral density in the energy transfer $\nu$ – the elastic scattering, the inelastic reactions ($\pi N, \pi\pi M, \eta N$ etc.) and resonances ($\Delta, \text{Roper,} S_{11}$, etc.), shallow inelastic scattering (SIS), and deep inelastic scattering (DIS) regions. To determine how large a $\nu$ is needed for DIS, we look at $W$, the total invariant mass of the hadronic state

$$W^2 = (q + p)^2 = m_p^2 - Q^2 + 2m_p\nu$$

(6)

The global analysis of the high energy lepton-nucleon and Drell-Yan experiments to extract the parton distribution functions (PDFs) usually make a cut with $W^2 > 10\text{ GeV}^2$. To be qualified in the DIS region, the energy transfer $\nu$ needs to be

$$\nu > 4.86\text{ GeV} + 0.533 (\text{GeV}^{-1}) Q^2$$

(7)
Figure 2: Three gauge invariant and topologically distinct insertions in the Euclidean-path integral formulation of the nucleon hadronic tensor where the currents couple to the same quark propagator. In the DIS region, the parton degrees of freedom are (a) the valence and connected sea (CS) partons $q^v + cs$, (b) the CS anti-partons $\bar{q}^{cs}$. Only $u$ and $d$ are present in (a) and (b) for the nucleon hadronic tensor. (c) the disconnected sea (DS) partons $q^{ds}$ and anti-partons $\bar{q}^{ds}$ with $q = u, d, s,$ and $c$.

Figure 3: Three other gauge invariant and topologically distinct insertions where the currents are inserted on different quark propagators. In the DIS region, they are higher-twist diagrams.
If we take $Q^2 = 4\text{GeV}^2$, this implies $\nu > 7\text{GeV}$. It is shown recently in a lattice calculation that small lattice spacing (e.g. $a \leq 0.04\text{fm}$) is needed to reach such high energy excitations \[17\].

It is shown \[12, 13, 14\] that, when the time ordering $t_f > t_2 > t_1 > t_0$ is fixed, the 4-point function $\text{Tr}(\Gamma e G_{\mu W_p}(t_0, t_1, t_2, t_f))$ can be grouped in terms of 6 topologically distinct and gauge invariant path-integral insertions as illustrated in Figs. 2 and 3 according to different Wick contractions among the Grassmann numbers in the two currents and the source/sink interpolation fields. They can be denoted as connected insertions (CI) (Fig. 2(a), Fig. 2(b), and Fig. 3(a)) where the quark lines are all connected and disconnected insertions (DI) (Fig. 2(c), Fig. 3(b), and Fig. 3(c)) where there are vacuum polarizations associated with the currents in disconnected quark loops. Note, these diagrams depict the quarks propagating in the non-perturbative gauge background which include the fluctuating gauge fields and virtual quark loops from the fermion determinant. Only the quark lines associated with the interpolations fields and currents are drawn in these quark skeleton diagrams.

At low energy lepton-nucleon scattering, all 6 diagrams in Figs. 2 and 3 contribute and they are not separable. For the elastic scattering case, the hadronic tensor $W_{\mu \nu}$ as a function of $Q^2$ is basically the product sum of the relevant nucleon form factors. For example, it is verified in a recent lattice calculation \[17\] that it is the sum of Fig. 2(a) and Fig. 3(a) that give rise to the square of the charges for the $u$ quarks in the proton in the forward limit when $J_\mu$ and $J_\nu$ are the charge current, i.e. $W_{44}(\vec{p} = \vec{q} = 0, \nu = 0)(u\text{quark}) = (2e_u)^2$, while the other diagrams are zero due to charge conservation. At low $\vec{q}$ and $\nu$ appropriate for a $\rho - N$ intermediate state, all connected insertions (CI) in Figs. 2(a), 2(b), and 3(a) contribute to the $\rho - N$ scattering. It is worth pointing out that Fig. 2(b) includes the exchange contribution to prevent the $u/d$ quark in the loop in Fig. 2(c) from occupying the same Dirac eigenstate in the nucleon propagator, enforcing the Pauli principle. In fact, Figs. 2(c) and Fig. 2(b) are analogous to the direct and exchange diagrams in time-ordered Bethe-Goldstone diagrams in many-body theory.

2.1 Parton Degrees of Freedom

In the DIS region (e.g. $Q^2 \geq 4\text{GeV}^2$ and $\nu > 7\text{GeV}$ in Eq. (7)) as illustrated in Fig. 1 insertions in Fig. 2 contain leading and higher twists (hand-bag diagrams), while those in Fig. 3 contain only higher twists (cat’s ears diagrams). As far as the leading-twist DIS structure functions $F_1, F_2$ and $F_3$ are concerned, the three diagrams in Fig. 2 are additive with contributions classified as the valence and sea quarks $q^{v+cs}$ in Fig. 2(a), the connected sea (CS) antiquarks $\bar{q}^{cs}$ in Fig. 2(b) and disconnected sea (DS) quark $q^{ds}$ and antiquarks $\bar{q}^{ds}$ in Fig. 2(c) \[12, 13, 14, 15\]. It was pointed out that the Gottfried sum rule violation comes entirely from the connected sea difference $\bar{u}^{cs} - \bar{d}^{cs}$ in the $F_2$ structure functions at the isospin symmetric limit \[12\].

Owing to the factorization theorem \[18\] which separates out the long-distance and short distance behaviors, the structure function $F_1$ of the hadronic tensor can be factorized as

$$F_1(x, Q^2) = \sum_i \int_x^1 \frac{dy}{y} C_i \left( \frac{x}{y}, Q^2, \frac{\mu_f^2}{\mu^2}, \alpha_s(\mu^2) \right) f_i(y, \mu_f, \mu^2), \quad (8)$$
where \( i \) is summed over \( q_i, \bar{q}_i, g \). \( C_i \) are the Wilson coefficients and \( f_i \) are the parton distribution functions (PDFs). \( \mu_f \) is the factorization scale, and \( \mu \) is the renormalization scale. In practice, the global fitting programs adopt the parton degree of freedoms as \( u, d, \bar{u}, \bar{d}, s, \bar{s} \) and \( g \). We see that from the path-integral formalism, each of the \( u \) and \( d \) have two sources, one from the connected insertion (CI) (Fig. 2(a)) and one from the disconnected insertion (DI) (Fig. 2(c)), so are \( \bar{u}, \bar{d} \) from Fig. 2(b) and Fig. 2(c). On the other hand, \( s \) and \( \bar{s} \) only come from the DI (Fig. 2(c)). In other words,

\[
\begin{align*}
 u &= u^{v+cs} + u^{ds}, & d &= d^{v+cs} + d^{ds} \\
 \bar{u} &= \bar{u}^{cs} + \bar{u}^{ds}, & \bar{d} &= \bar{d}^{cs} + \bar{d}^{ds}, \\
 s &= s^{ds}, & \bar{s} &= \bar{s}^{ds},
\end{align*}
\tag{9}
\]

This classification of the parton degrees of freedom (PDF) is richer than those in terms of \( q \) and \( \bar{q} \) in the global analysis in that there are two sources for the partons – \( q^{v+cs} \) and \( q^{ds} \) – and two sources for the antipartons – \( \bar{q}^{cs} \) and \( \bar{q}^{ds} \). They have different small \( x \) behaviors. For connected insertion (CI) part, \( q^{v+cs}, q^{cs} \sim x^{-1/2} \) where \( q = u, d \); whereas, for the disconnected insertion (DI) part, \( q^{ds}, \bar{q}^{ds} \sim x^{-1} \) where \( q = u, d, s, \bar{c}, \bar{s} \). It is discerning to follow these degrees of freedom in moments which further reveal the roles of CI and DI in nucleon matrix elements. They have been intensively studied in lattice calculations which are beginning to take into account all systematic corrections.

### 2.2 Moments of PDFs

The short-distance expansion of the current-current correlator in the nucleon in Eq. (3) has been carried out \cite{15}. After applying inverse Laplace transform in Eq. (4) and dispersion relation to convert the hadronic tensor to the Minkowski space, it is shown that the total results are the same as that of the operator product expansion. However, the Euclidean path-integral formulation of the current-current correlator is composed of several components. The leading-twist forward Compton amplitude \( T_{\mu\nu} \) corresponding to \( q^{v+cs} \) in Fig. 2(a) are expanded as

\[
T_{\mu\nu}(q^{v+cs}) = \sum_f e_f^2 \delta_{\mu\nu} p_\mu p_\nu \left\{ \sum_{\text{even}, n=2} \frac{(-2 q \cdot p)^{n-2}}{(Q^2)^{n-1}} A_f^n(CI) + \sum_{\text{odd}, n=3} \frac{(-2 q \cdot p)^{n-2}}{(Q^2)^{n-1}} A_f^n(CI) \right\},
\tag{10}
\]

where \( f \) indicates flavor. For the nucleon, it only involves \( u \) and \( d \) in the CI. In this case, \( A_f^n(CI) \) are defined through the renormalized connected insertion (CI) matrix element at \( \mu \)

\[
\langle p | \bar{\Psi} O_f^n \Psi | p \rangle_{CI}(\mu) = 2 A_f^n(CI)(\mu) (p_{\mu_1} p_{\mu_2} \cdots p_{\mu_n} \cdots \text{traces}).
\tag{11}
\]

where the renormalized operators \( O_f^n \) are

\[
O_f^n = Z_n(\mu) i \gamma_{\mu_1} \frac{(-i)}{2} \not{D}_{\mu_2} \not{D}_{\mu_3} \cdots \not{D}_{\mu_n} \cdots \text{traces},
\tag{12}
\]

where \( Z_n(\mu) \) is the renormalization constant. This is represented by the ratio of three-point functions illustrated in Fig. 4(a) with the insertion of the tower of \( O_f^n \) operators and the nucleon two-point function.
Similarly, the short-distance expansion for the CS antiparton in Fig. 2(b) results in a similar expression as in Eq. (10) with the substitution \( q \rightarrow -q \) and \( \mu \leftrightarrow \nu \). As a result, this leads to the even \( n \) terms minus the odd \( n \) terms instead of the sum as in Eq. (10), i.e.

\[
T_{\mu\nu}(\bar{q}^{cs}) = \sum_{\text{even}, n=2} \cdots A_f^n(\text{CI}) - \sum_{\text{odd}, n=3} \cdots A_f^n(\text{CI}).
\] (13)

In other words, the short-distance expansion of \( T_{\mu\nu} \) from Fig. 2(b) yields three-point functions with a series of insertions of the same operators \( \bar{\Psi} O_f^n \Psi \) except with a minus sign for the odd \( n \) terms. This is illustrated in Fig. 4(b). By the same token, the short-distance expansion for the DS parton/antiparton contribution in \( T_{\mu\nu} \) from Fig. 2(c) gives

\[
T_{\mu\nu}(q^{ds}/\bar{q}^{ds}) = \sum_{\text{even}, n=2} \cdots A_f^n(\text{DI}) \pm \sum_{\text{odd}, n=3} \cdots A_f^n(\text{DI}).
\] (14)

They have the same expression as \( T_{\mu\nu}(q^{v+cs}) \) and \( T_{\mu\nu}(\bar{q}^{cs}) \) except \( A_f^n(\text{DI}) \) are from the DI part of the matrix element

\[
\langle p|\bar{\Psi} O_f^n \Psi|p\rangle_{\text{DI}} = 2 A_f^n(\text{DI})(p_{\mu_1}p_{\mu_2}\ldots p_{\mu_n} - \text{traces}).
\] (15)

In this case, the leading twist expansion of the DS contribution to \( T_{\mu\nu} \) in Fig. 2(c) now leads to two series of forward matrix elements of DI. One is for \( T_{\mu\nu}(q^{ds}) \) with even plus odd \( n \) terms; the other is \( T_{\mu\nu}(\bar{q}^{ds}) \) with even minus odd \( n \) terms as given in Eq. (14). Both are represented in the three-point functions in Fig. 4(c). It is worth mentioning that \( T_{\mu\nu}(q^{v+cs}) \) in Eq. (10) and \( T_{\mu\nu}(q^{ds}) \) in Eq. (14) are the same as those derived from the contraction of the inner pair of the quark fields in the conventional operator product expansion of the time-ordered current-current product \( \bar{q}(x)\gamma_{\mu}q(x)\bar{q}(0)\gamma_{\nu}q(0) \). On the other hand, \( T_{\mu\nu}(\bar{q}^{cs}) \) in Eq. (13) and \( T_{\mu\nu}(\bar{q}^{ds}) \) in Eq. (14) are the same as those from the contraction of the outer pair of the quark fields in the current-current product. The only difference is that the path-integral formalism allows the separations into the CI and the DI.
In the operator product analysis, the $A_j^n$ are the moments of PDFs

$$A_j^n(CI) = M^n(CI) \equiv \int_0^1 dx \, x^{n-1}(q^{v+cs}(x, \mu) + (-1)^n \bar{q}^{cs}(x, \mu)), \quad (16)$$

$$A_j^n(DI) = M^n(DI) \equiv \int_0^1 dx \, x^{n-1}(q^{ds}(x, \mu) + (-1)^n \bar{q}^{ds}(x, \mu)). \quad (17)$$

When the parts in Eqs. (10), (13), and (14) are summed up, only the even $n$ terms of the OPE are left for the vector currents $J_\mu$ and $J_\nu$.

$$T_{\mu\nu} = T_{\mu\nu}(q_{v+cs}) + T_{\mu\nu}(\bar{q}_{cs}) + T_{\mu\nu}(q_{ds} + \bar{q}_{ds}) = 2 \sum_{\text{even, } n=2} \cdots (A_j^n(CI) + A_j^n(DI)). \quad (18)$$

This is the same as that derived from the ordinary OPE. However, what is achieved with the path-integral formulation is the separation of CI from DI, in addition to the separation of partons from antipartons. This separation facilitates the identification of the CS parton as the source of the Gottfried sum rule violation [12], and an extended set of evolution equations for separate $\bar{q}_{cs}(x, Q^2)$ and $\bar{q}_{ds}(x, Q^2)$ [27]. We should emphasize that, for a given moment, there is no more distinction between $q^{v+cs}$ and $\bar{q}^{cs}$, nor with $q^{ds}$ and $q^{ds}$. There are only CI and DI matrix elements.

### 2.3 Renormalization and evolution

The SU(3) flavor dependence of the moments is usually expressed in terms of iso-vector, flavor octet and flavor singlet. Here in the path-integral formulation, there are more moments that can be – and have been – evaluated on the lattice. For example, the renormalization matrix for the renormalized second moment $\langle x \rangle$ has the following structure

$$\begin{pmatrix}
\langle x \rangle_R^{u(CI)}(\mu) \\
\langle x \rangle_R^{d(CI)}(\mu) \\
\langle x \rangle_R^{u(DI)}(\mu) \\
\langle x \rangle_R^{d(DI)}(\mu) \\
\langle x \rangle_R^{G(DI)}(\mu)
\end{pmatrix} =
\begin{pmatrix}
Z_C & 0 & 0 & 0 & 0 & 0 \\
0 & Z_C & 0 & 0 & 0 & 0 \\
Z_D & Z_D & Z_C + Z_D & Z_D & Z_D & Z_{CG} \\
Z_D & Z_D & Z_D & Z_C + Z_D & Z_D & Z_{CG} \\
Z_D & Z_D & Z_D & Z_D & Z_C + Z_D & Z_{CG} \\
Z_{Gq} & Z_{Gq} & Z_{Gq} & Z_{Gq} & Z_{Gq} & Z_{GG}
\end{pmatrix}
\begin{pmatrix}
\langle x \rangle_R^{u(CI)}(\mu) \\
\langle x \rangle_R^{d(CI)}(\mu) \\
\langle x \rangle_R^{u(DI)}(\mu) \\
\langle x \rangle_R^{d(DI)}(\mu) \\
\langle x \rangle_R^{G(DI)}(\mu)
\end{pmatrix} \equiv
\begin{pmatrix}
\langle x \rangle_R^{u-\mu}(\mu) \\
\langle x \rangle_R^{u+\mu-2s}(\mu) \\
\langle x \rangle_R^{u+\mu+2s}(\mu) \\
\langle x \rangle_R^{G}(\mu)
\end{pmatrix} \quad \begin{pmatrix}
\langle x \rangle_R^{u-d}(\mu) \\
\langle x \rangle_R^{u+d-2s}(\mu) \\
\langle x \rangle_R^{u+d+s}(\mu) \\
\langle x \rangle_R^{G}(\mu)
\end{pmatrix} \quad (19)$$

After linear combinations of CI and DI matrix elements in the equations in Eq. (19), one can reduce them to those in in the flavor-SU(3) representation

$$\begin{pmatrix}
\langle x \rangle_R^{u-\mu}(\mu) \\
\langle x \rangle_R^{u+\mu-2s}(\mu) \\
\langle x \rangle_R^{u+\mu+2s}(\mu) \\
\langle x \rangle_R^{G}(\mu)
\end{pmatrix} =
\begin{pmatrix}
Z_C & 0 & 0 & 0 \\
0 & Z_C & 0 & 0 \\
0 & 0 & Z_C + N_f Z_D & N_f Z_{CG} \\
0 & 0 & Z_{Gq} & Z_{GG}
\end{pmatrix}
\begin{pmatrix}
\langle x \rangle_R^{u-d}(\mu) \\
\langle x \rangle_R^{u+d-2s}(\mu) \\
\langle x \rangle_R^{u+d+s}(\mu) \\
\langle x \rangle_R^{G}(\mu)
\end{pmatrix} \quad (20)$$

It should be noted that there are 6 observables in Eq. (19) (5 if one assumes isospin symmetry so that $\langle x \rangle_R^{u(DI)} = \langle x \rangle_R^{d(DI)}$), while there are 4 in Eq. (20). This means that, by
separating the CI and DI, the path-integral formulation has more information than that of the flavor classification. Since the lattice calculations are organized with separate CI and DI moments, it is natural to ask how to accommodate such a separation in the global analysis so that one can make a one-to-one comparison between the lattice results and those from the global fits. At the moment, the CS partons and DS partons are not separated in global analyses, one could not make such a comprehensive comparison and is only limited to the isovector and strangeness quantities.

Attempts have been made \cite{22, 23, 24, 25} to separate out the CS and DS partons by combining strange parton distribution from a HERMES experiment \cite{19}, \bar{u} + \bar{d} from the CT10 analysis \cite{20}, and the ratio \langle x \rangle_s / \langle x \rangle_u(DI) from lattice calculations \cite{21, 25}.

It has been pointed out \cite{27} that in order to have a direct one-to-one comparison with the \textit{11} parton distributions in Eq. (9) (including the glue distribution) from the hadronic tensor which can be calculated on the lattice \cite{15, 16, 17}, the NNLO evolution equations need to be extended to accommodate these partons. In certain cases, such as the moments \cite{17}, precise lattice calculations can be used to help constrain the global PDF analysis and the small \( x \) behavior. The extended evolution equations are worked out \cite{27} for the 11 parton distributions in Eq. (9) with an explicit separation of CS and DS. Due to the linear nature of the evolution equations, these equations can be combined and reduced to the present DGLAP equations with \( \bar{q}^{cs} \) and \( \bar{q}^{ds} \) merged into \( \bar{q} \). But, only through the fully separated CS and DS degrees of freedom in the extended evolution equations can the CS and DS be separated at different \( Q^2 \) \cite{27}. This aspect is essential for the global analysis of PDF to fit experimental data at different \( Q^2 \).

Another aspect of the separation of the CI from DI is shown in Eq. (19) where the zeros reflect the fact that the CI can mix into glue and DI, but not vice versa. There are no valence like partons in the strange and glue partons. This is reflected in the extended evolution equations \cite{27} and it turns out to be crucial in resolving the puzzles presented in introduction in Sec. 1 as we shall see later.

### 3 Feynman-\( x \) Approach

A number of approaches have been developed in recent years to calculate the PDFs in Feynman-\( x \) with lattice calculation \cite{28, 29, 30}. It was first pointed out by Ji \cite{28} that one can approximate a light-cone PDF by boosting a time independent quasi PDF defined on the lattice to a large momentum frame with an expansion in powers of the inverse hadron momentum. At leading twist, the boosted quasi PDF can be renormalized in the \( \overline{\text{MS}} \) scheme and factorized into the light-cone PDF and a perturbative matching coefficient. The matching coefficient can be calculated via the large momentum effective theory (LaMET) \cite{31}. The unpolarized quasi-PDF is defined on the lattice

\[
\bar{q}(x, P_z) \equiv \int_{-\infty}^{\infty} \frac{dz}{4\pi} e^{ix \cdot P_z} \langle P | \bar{\psi}(z) \Gamma U(z, 0) \psi(0) | P \rangle, \tag{21}
\]
where $\Gamma = \gamma_4$ or $\gamma_z$ and the Wilson line is
\[
U(z, 0) = P \exp \left( -ig \int_0^z dz' A_z(z') \right).
\] (22)

There are two path-integral diagrams associated with the four-point function in Eq. (21). As we can see in Fig. 3, they are again separated into connected insertion (CI) and disconnected insertion (DI) as in the Euclidean formulation of the hadronic tensor in Sec. 2. Unlike

![Diagram](a)

![Diagram](b)

Figure 5: Path-integral diagrams of quasi-PDF as defined in Eq. (21). The double lines represent the Wilson line operators. There are two diagrams – (a) for CI and (b) for DI, respectively.

the PDF defined on the light-cone which is boost invariant, the quasi-PDF in Eq. (21) depends on the nucleon momentum $P_z$. When $P_z$ is much larger than the nucleon mass $M$ and $\Lambda_{\text{QCD}}$, the quasi-PDF in the CI can be factorized into a matching coefficient and the PDF \[31, 32\]

\[
\bar{q}(x, P_z, \mu_R) = \int_{-1}^{1} \frac{dy}{\bar{y}} C \left( x, \frac{\mu_R}{\mu}, \frac{\mu}{P_z} \right) q(y, \mu) + O\left( \frac{M^2}{P_z^2}, \frac{\Lambda_{\text{QCD}}}{P_z^2} \right),
\] (23)

where $\mu_R$ is the renormalization scale and $\mu$ is the factorization scale.

Using the operator product expansion, the factorization theorem for the renormalized CI part of the quasi-PDF is derived \[33\]

\[
\bar{q}(x, \frac{\mu}{P_z}) = \int_{-1}^{1} \frac{dy}{\bar{y}} C \left( x, \frac{\mu}{\bar{y}|P_z|} \right) q(y, \mu),
\] (24)

which shows that the factorization formula for the quasi-PDF has $p_z = |y|P_z$ in the coefficient function $C$. As such, there are no moment relations between the light-cone PDF and the quasi-PDF.

We note that the target PDF $q(y, \mu)$ is inside the integral in Eq. (24), similar to the cases of global analysis in Eq. (8) and the hadronic tensor in Eq. (5). They all involve an inverse
Figure 6: Lattice calculation of quasi-PDF with LaMET for the connected insertion (CI). (a) is the polarized $\Delta u - \Delta d$ from LP3 at $\mu = 3$ GeV and (b) is the unpolarized $u - d$ from ETMC at $\mu = 2$ GeV.

problem. Like the global analysis, one can assume a functional form for $q(y, \mu)$ and fit the lattice data of the quasi-PDF $\tilde{q}(x, \mu)$. We show two recent lattice calculations of quasi-PDF in the CI from Fig. 5(a). Fig. 6(a) shows the calculation of the polarized PDF $(\Delta u - \Delta d)$ on a lattice with lattice spacing $a = 0.09$ and $\mu = 3$ GeV fm from the LP3 collaboration [34] and Fig. 6(b) shows the unpolarized PDF $(u - d)$ from a lattice with $a = 0.0938$ fm and $\mu = 2$ GeV from the ETMC collaboration [35]. Both of them are calculated at the physical pion mass and with one-loop matching from LaMET. To better control the errors at small $x$ with higher momenta and excited states, variational approaches [36] can be employed.

Since the light-cone parton distribution has support $-1 \leq x \leq 1$ with large enough $P_z$, it is different from those defined from the hadronic tensor which has support $0 \leq x \leq 1$. The light-cone PDFs with $x > 0$ correspond to partons from the hadronic tensor through the factorization in Eq. (8) and those with $x < 0$ correspond to antipartons from the hadronic tensor with a negative sign. As we mentioned in Sec. 2.3, partons in the CI have no mixing from the DS and gluons. Therefore, at the same $\overline{\text{MS}}$ scale $\mu$, the CI light-cone PDFs are identified as those from the hadronic tensor, i.e.

\[
q(x > 0, \mu)(\text{CI}) = \tilde{q}^{u+cs}(x, \mu), \\
q(x < 0, \mu)(\text{CI}) = -\tilde{q}^{cs}(|x|, \mu).
\]

(25)

It is clear from Fig. 6 that the CS antipartons in the region $x < 0$ are explicitly revealed. Similarly, one can make the corresponding identifications for the DS partons and antipartons in Eq. (9).

Another way to show that parton degrees of freedom in quasi-PDF with LaMET and those from the hadronic tensor are the same is to look at the operator product expansion. After renormalization to remove the power divergence from the Wilson line self-energy, the renormalized $\tilde{\psi}(z)\Gamma U(z,0)\psi(0)$ operator can be expanded in terms of the gauge-invariant
operators as $z^2 \rightarrow 0$

$$\psi(z)\Gamma U(z, 0)\psi(0)_R = \sum_{n=0}^{\infty} C_n(\mu^2 z^2) \frac{(-iz)^n}{n!} e_{\mu_1}...e_{\mu_n} O^n(\mu),$$  \hspace{1cm} (26)

where $O^n(\mu)$ is that given in Eq. \ref{12} and its matrix element defined in Eq. \ref{11}, with $A^n_f$ being the $n^{th}$ moments of the DPFs. In terms of the distribution on the light-cone, $A^n$ for the $u$ and $d$ flavors in the CI are

$$A^n(\mu)(CI) = \int_{-1}^{1} dx x^{n-1} q(x, \mu)(CI)$$  \hspace{1cm} (27)

In terms of the PDFs defined from the hadronic tensor in Eq. \ref{25}

$$A^n(\mu)(CI) = \int_{0}^{1} dx x^{n-1} \left( q^{v+cs}(x) - (-1)^{n-1} q^{cs}(x) \right).$$  \hspace{1cm} (28)

This is the same as Eq. \ref{16}. One can further use inverse Mellin transform to find $q^{v+cs}$ and $q^{cs}$ separately. One can carry out the inverse Mellin transform for $A^n$ for even and odd $n$ and obtain

$$q^{v+cs}(x) = \int_{c-i\infty}^{c+i\infty} dn x^{-n} A^n(n = \text{even}) + \int_{c-i\infty}^{c+i\infty} dn x^{-n} A^n(n = \text{odd})$$  \hspace{1cm} (29)

$$q^{cs}(x) = \int_{c-i\infty}^{c+i\infty} dn x^{-n} A^n(n = \text{even}) - \int_{c-i\infty}^{c+i\infty} dn x^{-n} A^n(n = \text{odd})$$  \hspace{1cm} (30)

They have the same even-odd patterns as those in Eqs. \ref{10} and \ref{13}. Similarly, one can show that the in the DI, the $x > 0/x < 0$ distribution is $q^{ds}/q^{ds}$. There are other Feynman-$x$ approaches to calculating PDFs on the lattice, such as pseudo-PDF by Radyushkin \cite{29} and lattice cross-section by Ma and Qiu \cite{30}. After renormalization and matching to the light-cone, any valid approach will have the CI moments expressed in Eq. \ref{27} and their parton degrees of freedom are also identified with those from the hadronic tensor.

As of now, all the lattice calculations with the Feynman-$x$ approaches report the $u - d$ combination in the CI. As we have shown in Sec. 2.3 that the glue and DI do not mix into the CI. Therefore, it is just meaningful to report the CI $u$ and $d$ distributions separately.

4 Resolving the puzzles of the valence parton definition

Once we have identified the parton degrees of freedom from the path-integral formalism of QCD, we are ready to answer the puzzles about the definition of the valence in Sec. 1. First of all, the quark loop in Figs. 2(c) or 5(b) has a separate flavor trace from that involving the interpolation field ($uud$ for the proton in this case) for the nuclear propagator, the partons in the loop do not have any knowledge of the content of the interpolation field and are, thus, not part of the valence. Therefore, the valence should be defined from the CI in Figs. 2(a) and 2(b) i.e.

$$q^v \equiv q^{v+cs} - q^{cs}$$  \hspace{1cm} (31)
Since the strange and charm partons do not have CI contributions, they are not part of the valence. The question whether the strange is part of the valence contribution as posted in Sec. 1 is answered by Eq. (31).

Regarding question 2 in Sec. 1, we see that the phenomenologically defined $q^{-}$ is not the valence $q^{v}$. Rather it also contains DS partons

$$q^{-} \equiv q - \bar{q} = q^{v+cs} - \bar{q}^{cs} + q^{ds} - \bar{q}^{ds} = q^{v} + q^{ds} - \bar{q}^{ds}. \quad (32)$$

The NNLO evolution equations with separate CS and DS have been developed for a maximum of 11 parton degrees of freedom, namely $u_{v}^{c}, \bar{u}_{c}, u_{ds}, \bar{u}_{ds}, d_{v}^{c}, \bar{d}_{c}, d_{ds}, \bar{d}_{ds}, s, \bar{s}$ and $g^{[27]}$. In view of the fact that $q^{-}$ is made of $q^{v}$ and $q^{ds} - \bar{q}^{ds}$, we find that that Eq. (1) is in fact a linear combination of two equations,

$$\frac{dq_{i}^{v}}{dt} = (P_{q_{v}q_{v}}^{c} - P_{q_{v}q_{\bar{q}}}^{c}) \otimes q_{i}^{v} \quad (33)$$

$$\frac{d(q_{i}^{ds} - \bar{q}_{i}^{ds})}{dt} = (P_{q_{v}q_{q}}^{d} - P_{q_{v}q_{\bar{q}}}^{d}) \otimes \sum_{k} (q_{k}^{ds} - \bar{q}_{k}^{ds}) + (P_{q_{v}q_{q}}^{d} - P_{q_{v}q_{\bar{q}}}^{d}) \otimes \sum_{k} q_{k}^{v} \quad (34)$$

where we have used $P_{ii}^{c} = P_{i\bar{i}}^{c} = P_{q_{v}q_{v}}^{c}$, $P_{ik}^{c} = P_{i\bar{k}}^{c} = P_{q_{v}q_{q}}^{c}$, $P_{ik}^{d} = P_{i\bar{k}}^{d} = P_{q_{v}q_{q}}^{d}$, and $P_{i\bar{k}}^{d} = P_{i\bar{k}}^{d} = P_{q_{v}q_{\bar{q}}}^{d}$ due to flavor independence of the kernel $P$. We have also re-labeled $P_{q_{v}q_{q}}^{v} / P_{q_{v}q_{\bar{q}}}^{v}$ which indicates valence/sea in Eq. (1) to $P_{q_{v}q_{q}}^{c} / P_{q_{v}q_{\bar{q}}}^{c}$ to denote CI/DI.

It is clear from Eq. (33) that, with the proper definition of $q^{v}$ in Eq. (31), there is no more valence flavor mixing as for $q^{-}$ in Eq. (1). The evolution of the non-valence $q_{i}^{ds} - \bar{q}_{i}^{ds}$ in Eq. (34) has contributions from $q^{ds} - \bar{q}^{ds}$ and the valence $q^{v}$ with different flavors. Being $O(\alpha_{s}^{3})$, the kernel $P_{q_{v}q_{q}}^{d} - P_{q_{v}q_{\bar{q}}}^{d}$ is small, but one needs to take into account the possibility of sizable intrinsic strange $[5, 6]$ and charm asymmetries $[4, 7]$ which implies that $q^{ds} - \bar{q}^{ds}$ for $q = u, d$ might be non-zero and larger in magnitude than those of the strange and charm.

### 5 Are strange partons necessarily in the disconnected insertion?

After the puzzles over the definition of the valence parton are resolved, there is a lingering question as to why the strange and charm partons appear as the disconnected sea in the disconnected insertions only. Since the physical mass and matrix elements do not depend on the interpolation field, as long as it has the right quantum numbers and a non-zero overlap with the hadronic state under study, lattice practitioners usually adopt $uud$ interpolation field with $J^{P} = 1/2^{+}$ and $I = 1/2$ for the proton for simplicity. In this case, the non-valence strange and charm partons can only appear in DI. However, one could question if this is a special case due the restricted selection of the interpolation field. What if $\bar{s}s$ in included in the interpolation field in addition to $uud$? Would that entail strange to be a part of the CI and, perhaps, a part of the valence?
To answer this question, we shall prove that the strange and charm will necessarily be in DI with an example of interpolation field which includes the strange, i.e. $uud\bar{s}s$. As show in Fig. 7(a) the two-point function for $uud\bar{s}s$ has two path-integral diagrams due to the two Grassmann number contractions. Fig. 7(a) in the left panel has 5 valence quarks at all times between the source and the sink. When time separation $\tau = t_f - t_0$ is large, this part of the 2-pt correlator will have an asymptotic behavior

$$C_{2pt}^a(\tau) = W_{5q} e^{-M_{5q}\tau} + \ldots$$

(36)

where ... is for excited states. Having more valence quarks (one can count the minimum number of quark propagators in a time slice) than that of the $uud$ interpolation field, $M_{5q}$ will be higher than $M_N$, the nucleon mass. This is so, because the quark counting rule prescribes $\sim 300/500$ MeV constituent mass for each additional $q/s$ ($q = u, d$) quark. This is verified with a lattice calculation with the $uud\bar{s}s$ interpolator, where the $\bar{s}s$ is in the scalar channel. This is also consistent with the recent lattice calculation which shows that the renormalized quark mass $m^R$ in the RI/MOM scheme with Landau gauge rises up to approach $\sim 300$ MeV for the scale below $\sim 500$ MeV. It coincides with the trace anomaly matrix element at different scales. Due to limited statistics, this is verified down to $\mu = 1.3$ GeV and has prompted the suggestion that trace anomaly and chiral symmetry breaking could be the origin of the constituent quark mass in the quark model. Therefore, one expects the mass of the 5-quark state to be higher than the nucleon, a 3-quark state, by about 600 MeV.

The 2-pt function also has an insertion with $\bar{s}s$ annihilations in Fig. 7(b). Since the path-integral includes all possible paths, there are cases where the two $\bar{s}s$ do not overlap, leaving

\footnote{The only exceptions we know are the scalar mesons below 1 GeV, which are believed to be the $Q^2\bar{Q}^2$ tetraquark mesoniums in the MIT bag model and the potential model. They are verified in lattice calculations. These nonet mesoniums are below the $qq$ nonet above 1 GeV.}

Figure 7: 2-pt correlators for the $uud\bar{s}s$ interpolation field. (a) for the case where all 5 valence quarks propagate from the source to the sink; (b) for the case with $\bar{s}s$ annihilations.
a gap in time which allows the 3-quark nucleon to emerge. In this case, the lowest mass state is the nucleon and the correlator for this part is

\[ C_{2\text{pt}}(\tau) = W_N e^{-M_N \tau} + W'_{5q} e^{-M'_{5q} \tau} - W_{5q} e^{-M_{5q} \tau} + \ldots \] (37)

where \( M'_{5q} \) is the full 5-quark state mass of the total \( C_{2\text{pt}}(\tau) \) which is still an excited state of the nucleon. With \( \Delta M = M'_{5q} - M_N > 0 \), \( C_{2\text{pt}}(\tau) \) is dominated by the nucleon state at large \( \tau \).

The strangeness matrix element \( \langle N|s\Gamma s|N \rangle \) is calculated from the ratio of the 3-pt function to the 2-pt function. There are several contributions to the relevant 3-pt function \( C_{3\text{pt}}(t_f - t, t - t_0) \) as illustrated in Fig. 8. Inserting intermediate states between the source

\[ \frac{C_{3\text{pt}}(t_f - t, t - t_0)}{C_{2\text{pt}}(t_f - t_0)} = \frac{W_{5q}}{W_N} \langle 5q|\bar{s}\Gamma s|5q \rangle e^{-\Delta M \tau} + \sqrt{\frac{W_{5q}}{W_N}} \left( e^{-\Delta M (t_f - t)} + e^{-\Delta M (t - t_i)} \right) \langle 5q|\bar{s}\Gamma s|N \rangle + \langle N|\bar{s}\Gamma s|N \rangle + \ldots \] (39)

for large time separations. The first term on the right is from Fig. 8(a) which has 5 valence quarks. Its ratio involves the matrix element \( \langle 5q|\bar{s}\Gamma s|5q \rangle \) and an exponential factor \( e^{-\Delta M \tau} \) which vanishes at large \( \tau \). Similarly, the second term from Fig. 8(b) vanishes when \( t_f - t \) and \( t - t_i \) are large. The third term which survives large time separation is the nucleon matrix element that we want. It still comes from the DI and is independent of the interpolation field.

This example serves the purpose to prove that the strange and charm partons and their moments in the nucleon only contribute in the DI.
6 Summary

We show, in this work, that the problems posed by the phenomenological definition of the valence parton as $q - \bar{q}$ in NNLO evolution is resolved by the appropriate valence definition which involves only the parton and antipartons in the connected insertions from the Euclidean path-integral formulation of the hadronic tensor and the Feynman-$x$ approaches to PDFs. Since the path-integral formulation affords the separation of the connected and disconnected insertions, a salient feature of the formulation, a total of 11 parton degrees of freedom are revealed, which are more than the ones (7 which are $u, \bar{u}, d, \bar{d}, s, \bar{s},$ and $g$) from the existing global analyses. These parton degrees of freedom in the hadronic tensor, a Bjorken-$x$ approach, are shown to be the same as those from the Feynman-$x$ approaches via OPE (short distance Taylor expansion in the path-integral formalism). It is further proved that the non-valence strange and charm PDFs and their moments only contribute through the DI.

It is encumbered upon global analyses to disentangle the connected sea from the disconnected sea through the extended evolution equations [27], so that lattice results can be compared to them for each degree of freedom. As for the moments, where precise lattice results are beginning to be available with all systematic errors taken into account, it is a good testing ground to make benchmark comparison between lattice calculations and experiments. With the CS and DS separated in global fits, the CI moments for the $u$ and $d$ and DI moments for $u, d$ and $s$ can be directly compared with lattice calculations, instead of being restricted to only the isovector and strange matrix elements.
