Abstract: When a phase singularity is suddenly imprinted on the axis of an ordinary Gaussian beam, an optical vortex appears and starts to grow radially, by effect of diffraction. This radial growth and the subsequent evolution of the optical vortex under focusing or imaging can be well described in general within the recently introduced theory of circular beams, which generalize the hypergeometric-Gaussian beams and which obey novel kinds of ABCD rules. Here, we investigate experimentally these vortex propagation phenomena and test the validity of circular-beam theory. Moreover, we analyze the difference in radial structure between the newly generated optical vortex and the vortex obtained in the image plane, where perfect imaging would lead to complete closure of the vortex core.

1. Introduction

Research on the properties of optical vortices started with the seminal work of J. Nye and M. Berry [1]. There, the optical vortex was defined as a line along which the phase of the electromagnetic field is indeterminate, namely a line on which the intensity is zero. Beams carrying a defined photon value of the orbital angular momentum (OAM) are characterized by an optical vortex on the beam axis: the phase integration around the vortex divided by $2\pi$ gives an integer value, $\ell$, corresponding to the OAM content of the beam (per photon).

The observation that Laguerre-Gaussian (LG) modes have a well-defined OAM [2] has prompted, in the last decades, the investigation of the properties of beams carrying OAM and the possible techniques to generate, manipulate and analyze them. Nowadays, several devices are used to generate OAM beams: spiral phase plates [3], diffractive elements such as holograms [4] or spiral Fresnel lenses, cylindrical lenses, spatial light modulators and $q$-plates [5, 6, 7] (see [8] for a general review on the devices used to generate OAM).

Each of them, applied to a plane wave (or to a Gaussian beam), generates an optical vortex by multiplying the field by the phase profile $\exp(i\ell \phi)$, where $\phi$ is the angular coordinate along the plane transverse to the propagation. For ideally thin elements, this occurs with no other alterations of the beam field profile at the device output plane (sudden approximation). The study of the dynamic of an optical vortex has important applications in many fields, such as long distance free-space propagation [9, 10] or microscopy with OAM beams. The first study on the generation of an optical vortex [11] investigated the creation of filaments and the possibility of having vortex sizes two orders of magnitude smaller than the overall beam size. The propagation features of beams with OAM were studied in [12] and recently, a general theorem on the divergence of vortex beam was demonstrated [13]. In [14], the far-field intensity distribution obtained with plane waves or Gaussian beams impinging on a phase plate was derived, while [15] theoretically studied the propagation of a Gaussian beam on which a fractional vortex plate is applied. In [16], the Hypergeometric-Gaussian (HyGG) modes were introduced and it was shown that they can be obtained by applying the singular phase factor to a Gaussian-parabolic transmittance profile.

However, the different studies lack a comprehensive model for the vortex propagation through generic systems. Here we fill this gap by presenting an analytical model that quantitatively describes birth, evolution and closure of an optical vortex passing through an optical system that includes free space and two lenses. We also experimentally verified the validity of this model. The main tool that we use is the recently introduced family of Circular beams (CiBs) [17, 18], representing a very general solution of the paraxial wave equation with OAM. The use of CiBs is motivated by their simple transformation law under a generic ABCD optical...
A generic ABCD system is studied. In particular, as we will show, the parameter \( |q| \) of the optical system in terms of \( (1) \) by the transformation

Fig. 2. “Birth” of the optical vortex. In the first row we show the experimental intensity patterns obtained after the $q$-plate placed at the beam waist location at various propagation distances $d$. The data should be compared with the theoretical CiB model shown in the second row. In the third row we show the corresponding Laguerre-Gauss mode with the same $z_0$ and beam waist located at $d = 0$. The degree of agreement between the two models and the experiment is measured by the reported similarity values, $S$, given in each panel and shown in the right inset for different values of $d$.

using $(q_0, \xi)$ as beam parameters, the ABCD transformation can be rewritten as follows:

$$q_0 \rightarrow \frac{Aq_0 + B}{Cq_0 + D}, \quad \xi \rightarrow \frac{Cq_0 + D}{Cq_0 + D} \xi.$$  

(2)

It is worth noticing that, by the above transformation, the absolute value of $\xi$ and the normalization $N$ are invariant. Then, the parameter $|\xi|$ identifies an “equivalence class” of CiBs under generic ABCD optical transformations: beams with different $|\xi|$’s cannot be obtained as input and output of any real ABCD system. Moreover, as noticed in [13], the value of the parameter $|\xi|$ determines the constraints on $p$ to achieve square integrability. When $|\xi| < 1$ the beam is square integrable $\forall p$; when $|\xi| = 1$ it is required that $\Re(p) > -1 - |\ell|$; when $|\xi| > 1$ square integrability imposes $p/2 \in \mathbb{N}$. Finally, $\xi$ does not change in free-space propagation. Then, we believe that the description of CiBs in terms of $(q_0, \xi)$ offers a clearer view of their properties during generic optical transformations.

The beams that can be easily experimentally generated by using phase plates or $q$-plates correspond to CiBs with $|\xi| = 1$: indeed, by applying the phase factor $e^{i\phi}$ to a Gaussian beam with a given $z_0$ at a distance $\Delta$ from its waist plane, the CiBs with $\xi = \frac{z_0 - i\Delta}{z_0 + i\Delta}$ and $p = -|\ell|$ is generated [16, 18]. After straightforward calculations from [17], such beams can be written as:

$$\text{CiB}^{|q_0, q_0\rangle} = \frac{\Gamma(|\ell|/2 + 1)}{|\ell|!} \left(-\frac{r^2}{\chi^2}\right)^{|\ell|/2} G(r) {_1F_1}\left(\frac{|\ell|}{2}, |\ell| + 1; \frac{r^2}{\chi^2}\right) e^{i\phi}, \quad \text{when } |\xi| = 1.$$  

(3)

The beam in (3), that carries $\ell$ units of OAM, is quite different from one of the well known (and very much used) LG modes. Indeed, the intensity of a $LG_{0, \ell}$ mode presents an intensity pattern that has always an hole in the center, even at its waist location, while in the beam of eq. (3) the vortex is absent at a distance $\Delta$ from its waist plane, but starts to grow during propagation. The goal of our experiment is then to study the evolution of a beam generated by applying the phase $e^{i\phi}$ to a Gaussian beam and to compare it with the CiB model.
Fig. 3. **Left**: Focusing of an optical vortex by a lens. Experimental (upper row) and theoretical (lower row) intensity patterns obtained at various distances \(d\) from the focusing lens. **Right**: Quasi-closure of the optical vortex occurring when a real image of the vortex source is created by a lens system. Experimental (upper row) and theoretical (lower row) intensity patterns obtained at various distances \(d\) from the second lens. The medium panel for \(d = 200\) mm corresponds to the image plane.

3. The experiment

The experimental setup is shown in Fig. 1. A circular polarized Gaussian beam impinges on a \(q\)-plate placed on the beam waist. The optical vortex is then generated (the same results could be obtained with any device able to imprint the phase profile \(e^{i\phi}\)). The obtained beam propagates through an optical system composed of two lenses with focal lengths \(f_1\) and \(f_2\) respectively. We measured the intensity pattern of the beam by a CCD camera across four different zones, labeled as A, B, C and D (Fig. 1), and compared the results with the model provided by the CiBs. As a reference, we first measured the properties of the impinging Gaussian beam at wavelength 810 nm without \(q\)-plate. Taking \(z = 0\) the location of the beam waist, we measured the beam intensity at seven different distances \(d\), ranging from 10 cm to 1120 cm. From them we derived the beam waist \(w_0 = 850 \pm 10\) µm, corresponding to a Rayleigh distance \(z_0 = 2.80 \pm 0.07\) m.

To compare the theoretical and experimental intensity patterns we used the similarity, defined as 
\[
S = \frac{\sum_{x} \left( I_{x,y}^{th} - I_{x,y}^{exp} \right) / \sqrt{\sum_{x,y} (I_{x,y}^{th})^2}}{\sum_{x,y} (I_{x,y}^{exp})^2} \right)
\]
where \(I_{x,y}^{exp}\) and \(I_{x,y}^{th}\) are the experimental and theoretical intensities at point \((x,y)\) respectively. In all the cases we measured \(S > 0.98\).

We then placed a \(q\)-plate with \(q = 1/2\) at the beam waist location, to observe the “birth” of the optical vortex: this corresponds to the “zone B” of Fig. 1. As predicted by the CiBs model, the vortex, related to the phase singularity on the beam axis, starts growing after the \(q\)-plate. After the propagation across a small distance, of the order of \(z_0/10\), the vortex diameter stabilizes to a size of the order of half beam diameter. The “birth” of the optical vortex is shown in Fig. 2 where we compare the experimental intensity patterns with the theoretical model of [3] with \(\ell = 1\), \(\xi = 1\) and \(q_0(d) = d + iz_0\). The good agreement between observed intensities and the predictions is proved by the similarities, always greater than 0.95: we here stress that no fitting parameter was employed in the theoretical model. Indeed, we used as Rayleigh distance the value \(z_0 = 2.8\) m obtained in the previous measurement. The parameter \(d\) reported in the top of Fig. 2 corresponds to the measured distance from the \(q\)-plate. In Fig. 2 we also show the intensity of a LG mode with \(p = 0\), \(\ell = 1\) and the same \(z_0 = 2.8\) m, to demonstrate the differences between the experimental generated beam, its theoretical model represented by the CiBs and the widely used LG approximation. While the beam resembles a Laguerre-Gauss mode in the far field, in the near field (up to a distance of \(~z_0/10\) from the \(q\)-plate) the LG approximation fails to correctly model the beam properties, as quantified by the low values of the similarities. In particular, the “birth” of the optical vortex cannot be modeled by a LG mode, since, for such beams, the vortex is present along all transverse planes during propagation, as...
shown for instance by the LG intensity patterns at \(d = 10\ mm\) in Fig. 2. The same conclusions were obtained in the theoretical analysis of [21]: indeed, it is worth noticing that the subclass of CiB with \(\xi = 1\) and \(p = -|\ell|\) corresponds to the “Kummer beams” defined in [21]. However, the formulation in terms of CiBs, allows for a complete study of the propagation through generic optical systems, as we now demonstrate. Indeed, we also measured the beam evolution after a lens with focal length \(f_1 = 510\ mm\), corresponding to the “zone C” of Fig. 1. The lens was placed at distance \(d_1 = 150\ mm\) from the \(q\)-plate plane and now we indicate by \(d\) the distance from the lens. By the ABCD law, the beam parameters \((q_0(d), \xi_C)\) in zone C can be calculated from \((i\xi_0, 1)\) by the matrix \(M = \begin{pmatrix} 1-d/f_1 & d+d_1-2d_1/f_1 \\ -1/f_1 & 1-d_1/f_1 \end{pmatrix}\), obtaining

\[
q_0(d) = \frac{(d+d_1)f_1-dd_1+i\xi_0(f_1-d)}{f-d_1-i\xi_0}, \quad \xi_C = \frac{f_1-d_1+i\xi_0}{f_2-d_1-i\xi_0}.
\]

In zone C, as expected, \(\xi_C\) does not depend on \(d\). We show the comparison between the measured and calculated intensity patterns obtained at different distances \(d\) from the lens in the left panel of Fig. 3. The theoretical intensity patterns were evaluated by inserting in the CiBs of (3) the above values of \(q_0(d)\) and \(\xi(d)\). Four of the eight measured patterns and the corresponding similarities \(S\) are shown (the lowest of the eight measured similarity is 0.885): they demonstrate that CiB correctly models the propagation of such beam. We notice that the chosen position of the lens is such that no real imaging of the \(q\)-plate takes place in zone C.

We finally observed the beam in the “zone D”, that is after a second lens leading to the formation of a real image of the \(q\)-plate vortex source. In this case we used \(f_1 = 300\ mm\) and \(f_2 = 200\ mm\), with the lens \(f_1\) placed at distance \(d_1 = f_1\) from the \(q\)-plate and the lens \(f_2\) placed at distance \(f_1 + f_2\) from the first lens. We now indicate by \(d\) the distance after the lens \(f_2\). The ABCD matrix in this case is given by \(M = \begin{pmatrix} -f_2/f_1 & f_1-df_1/f_2 \\ 0 & -f_1/f_2 \end{pmatrix}\) corresponding to \(q_0(d) = d - f_1 + i\xi_0f_2^2/f_1^2\) and \(\xi_0 = 1\). In Fig. 3(right) we show three of the seven measured patterns and the corresponding similarities \(S\) (now the lowest measured similarity was 0.928). It is worth noticing the almost complete closure of the vortex: at the plane \(d = 200\ mm\) the vortex at the center almost completely disappears, even if the OAM content is still non-vanishing. The disappearance is actually not complete: a more accurate analysis (to be reported elsewhere) shows that the vortex radius reduces to a minimum value that depends on the numerical aperture of the optical imaging system, according to the standard resolution limits imposed by wave theory. However, this minimum vortex size can easily be orders of magnitude smaller than the beam size in the same plane. We further notice that an approximate theory based on LG vortex beams does not describe properly this vortex imaging phenomenon.

4. Conclusions

We have studied the generation and the propagation of an optical vortex created by superimposing an azimuthal phase pattern imprinted by a \(q\)-plate on a Gaussian beam. The application of such a phase mask is the principle on which all current approaches to generate and measure OAM eigenstates (spiral phase plates, fork holograms, \(q\)-plates) are based. By using an optical system with two lenses, we have experimentally verified for the first time the recently introduced ABCD law for Circular beams [17]. Our results demonstrate that the CiBs are very useful to analytically model the propagation through a generic optical system of OAM beams. We stress that many well known beams carrying OAM are included in the CiB family with particular values of the beam parameters. The accuracy of the \(q\)-plate in the generation of the singular phase profile \(\exp(i\ell\phi)\) to the beam was essential to generate a highly stigmatic beam that perfectly matches the theoretical predictions.
