Abstract

We provide a new lower bound on the number of \((\leq k)\)-edges of a set of \(n\) points in the plane in general position. We show that for \(0 \leq k \leq \lfloor \frac{n-2}{2} \rfloor\) the number of \((\leq k)\)-edges is at least

\[
E_k(S) \geq 3 \binom{k+2}{2} + \sum_{j=\lfloor \frac{k}{2} \rfloor}^{k} (3j - n + 3),
\]

which, for \(k \geq \lfloor \frac{n}{4} \rfloor\), improves the previous best lower bound in [7].

As a main consequence, we obtain a new lower bound on the rectilinear crossing number of the complete graph or, in other words, on the minimum number of convex quadrilaterals determined by \(n\) points in the plane in general position. We show that the crossing number is at least

\[
\left( \frac{41}{108} + \varepsilon \right) \binom{n}{4} + O(n^3) \geq 0.379631 \binom{n}{4} + O(n^3),
\]

which improves the previous bound of \(0.37533 \binom{n}{4} + O(n^3)\) in [7] and approaches the best known upper bound \(0.38058 \binom{n}{4}\) in [4].

The proof is based on a result about the structure of sets attaining the rectilinear crossing number, for which we show that the convex hull is always a triangle.

Further implications include improved results for small values of $n$. We extend the range of known values for the rectilinear crossing number, namely by $\tau(K_{19}) = 1318$ and $\tau(K_{21}) = 2055$. Moreover we provide improved upper bounds on the maximum number of halving edges a point set can have.

**Keywords:** Rectilinear crossing number. Halving edges. $j$-edges. $k$-sets.

1 Introduction

Given a graph $G$, its *crossing number* is the minimum number of edge crossings over all possible drawings of $G$ in the plane. Crossing number problems have both, a long history, and several applications to discrete geometry and computer science. We refrain from discussing crossing number problems in their generality, but instead refer the interested reader to the early works of Tutte [21] or Erdős and Guy [13], the recent survey by Pach and Tóth [20], or the extensive online bibliography by Vrt'o [22].

In 1960 Guy [16] started the search for the *rectilinear crossing number* of the complete graph, $\tau(K_n)$, which considers only straight-edge drawings. The study of $\tau(K_n)$ is commonly agreed to be a difficult task and has attracted a lot of interest in recent years, see e.g. [2, 3, 7, 10, 19]. In particular, exact values of $\tau(K_n)$ were only known up to $n = 17$, see [4], and also the exact asymptotic behavior is still unknown. Several relations to other structures, like for example $k$-sets, have been conjectured by Jensen [17]. Furthermore, it has been shown by Lovász et al. [19] that if we denote by $E_k(S)$ the number of $(\leq k)$-edges of $S$ and by $\tau(S)$ the number of crossings that appear when the complete graph is drawn on top of $S$ (equivalently, the number of convex quadrilaterals in $S$), then

$$\tau(S) = \sum_{k < \frac{n-2}{2}} (n - 2k - 3) E_k(S) + O(n^3).$$  \hspace{1cm} (1)

It may be surprising that until very recently no results about the combinatorial properties of optimal sets were known. Motivated by this, we start our study considering structural properties of point sets minimizing the number of crossings, that is, attaining the rectilinear crossing number $\tau(K_n)$. Relations are obtained by using basic techniques, like e.g. continuous motion and rotational sweeps. In particular, in Section 2 we investigate the changes of the order type of a point set when one of its points is moved. We define suitable moving directions which allow us to decrease $\tau(K_n)$, concluding that point configurations attaining the rectilinear crossing number have a triangular convex hull. Independently, and using different techniques, this result has been extended to pseudolinear drawings by Balogh et al. [8].

In Section 3, and using the same technique of continuous motion, we show that when proving a lower bound for $(\leq k)$-edges it can be assumed that the set has a triangular convex hull. Based on this, we give a really simple proof of the known bound $3\binom{k+2}{2}$, tight in the range $k \leq \left\lfloor \frac{n}{3} \right\rfloor - 1$ and, finally, we obtain a new bound for $k \geq \left\lfloor \frac{n}{3} \right\rfloor$ which improves the previous best lower bound obtained by Balogh and Salazar [7]: We show that, for $0 \leq k < \left\lfloor \frac{n-2}{2} \right\rfloor$, the number of $(\leq k)$-edges of a set of $n$ points in the plane in general position is at least

$$3\binom{k+2}{2} + \sum_{j=\left\lfloor \frac{n}{3} \right\rfloor}^{k} (3j - n + 3).$$
According to whether \( n \) is divisible by 3 or not, for \( k \geq \lfloor \frac{n}{3} \rfloor \) this bound can be written as follows:

\[
3 \left(\frac{k + 2}{2}\right) + 3 \left(\frac{k - \frac{n}{3} + 2}{2}\right) \quad \text{if} \quad \frac{n}{3} \in \mathbb{N}
\]

\[
3 \left(\frac{k + 2}{2}\right) + \frac{1}{3} \left(3k - n + 5\right) \quad \text{if} \quad \frac{n}{3} \notin \mathbb{N}.
\]

If we plug our new lower bound for \((\leq k)\)-edges in Equation (1), we get

\[
\text{cr}(K_n) \geq \left(\frac{41}{108} + \varepsilon\right) \binom{n}{4} + O(n^3) \geq 0.379631 \binom{n}{4} + O(n^3),
\]

that improves the best previous lower bound of \(0.37533 \binom{n}{4} + O(n^3)\) obtained by Balogh and Salazar [7] and approaches the best known upper bound of \(0.38058 \binom{n}{4}\) by Aichholzer and Krasser [4].

For small values of \( n \) the rectilinear crossing number is known for \( n \leq 17 \), see [4] and references therein. Our results imply that some known configurations of [2] are optimal. We thus extend the range of known values for the rectilinear crossing number by \(\text{cr}(K_{19}) = 1318\) and \(\text{cr}(K_{21}) = 2055\). Moreover our results confirm the values for smaller \( n \), especially \(\text{cr}(K_{17}) = 798\), which have been numerically obtained in [4]. Finally we provide improved upper bounds on the maximum number of halving lines that a set of \( n \) points can have.

### 2 Minimizing the number of rectilinear crossings

Let \( S = \{p_1, \ldots, p_n\} \) be a set of \( n \) points in the plane in general position, that is, no three points lie on a common line. It is well known that crossing properties of edges spanned by points from \( S \) are exactly reflected by the order type of \( S \), introduced by Goodman and Pollack in 1983 [15]. The order type of \( S \) is a mapping that assigns to each ordered triple \( i, j, k \) in \( \{1, \ldots, n\} \) the orientation (either clockwise or counterclockwise) of the point triple \( p_i, p_j, p_k \).

Consider a point \( p_1 \in S \) and move it in the plane in a continuous way. A change in the order type of \( S \) occurs if, and only if, the orientation of a triple of points of \( S \) is reversed during this process. This is the case precisely if \( p_1 \) crosses the line spanned by two other points, say \( p_2 \) and \( p_3 \), of \( S \). This event has been considered previously in [5] in the context of studying the change in the number of \( j \)-facets under continuous motion of the points, and it is called a mutation.

Assume that at time \( t_0 \) the three points \( p_1, p_2, p_3 \) are collinear and that the orientation of the triple at time \( t_0 + \varepsilon \) is inverse to its orientation at time \( t_0 - \varepsilon \) for some \( \varepsilon > 0 \), which can be chosen small enough to guarantee that the orientation of the rest of triples does not change in the interval \( [t_0 - \varepsilon, t_0 + \varepsilon] \). Let us assume that during the mutation \( p_1 \) crosses the line segment \( p_2p_3 \) as indicated in Figure 1 otherwise we can interchange the role of \( p_1 \) and \( p_2 \) (or \( p_3 \), respectively). We say that \( p_1 \) plays the center role of the mutation.

We call the above defined mutation a \( k \)-mutation if there are \( k \) points on the same side of the line through \( p_2 \) and \( p_3 \) as \( p_1 \), excluding \( p_1 \). Our first goal is to study how mutations affect the number of crossings of \( S \), that is, the number of crossings of a straight-line embedding of \( K_n \) on \( S \). Note that we are considering only rectilinear crossings.

**Lemma 1.** A \( k \)-mutation increases the number of crossings of \( S \) by \( 2k - n + 3 \).
Figure 1: The point $p_1$ crosses over the segment $p_2p_3$, changing the orientation of the triple $p_1,p_2,p_3$.

Proof. By definition of the $k$-mutation, the only triple of points changing its orientation is $p_1,p_2,p_3$. Thus precisely the $n - 3$ quadruples of points of $S$ including this triple inverse their crossing properties. Observe that at time $t_0 - \epsilon$ the shaded region in Figure 1 has to be free of points of $S$. Therefore, any of the $n - k - 3$ points opposite to $p_1$ with respect to the line through $p_2$ and $p_3$ produced a crossing together with $p_1$ and the segment $p_2p_3$. On the other hand, none of the $k$ points on the same side as $p_1$ does. This situation is precisely inverted after the flip and hence we get rid of $n - k - 3$ crossings, but generate $k$ new crossings.  

Since we know how mutations affect the number of crossings, we are now interested in good moving directions. A point $p \in S$ is called extreme if it is a vertex of the convex hull of $S$. Two extreme points $p,q \in S$ are called non-consecutive if they do not share a common edge of the convex hull of $S$. We define a halving ray $\ell$ to be an oriented line passing through one extreme point $p \in S$, avoiding $S \setminus \{p\}$ and splitting $S \setminus \{p\}$ into two subsets of cardinality $\frac{n}{2}$ and $\frac{n-2}{2}$ for $n$ even and $\frac{n-1}{2}$ each for $n$ odd, respectively. Furthermore, we orient $\ell$ away from $S$: For $H$ a half plane through $p$ containing $S$, the ‘head’ of $\ell$ lies in the complement of $H$ and the ‘tail’ of $\ell$ splits $S$.

Lemma 2. Let $p$ be an extreme point of $S$ and $\ell$ be a halving ray for $p$. If $p$ is moved along $\ell$ in the given orientation, every mutation decreases the number of crossings of $S$.

Proof. For the whole proof refer to Figure 2. First, we observe that $p$ has to be involved in any mutation and the center role is played by another point $q \in S$, since $p$ is extreme.
$r \in S$ be the third point involved in the mutation, so that $q$ crosses over the segment $pr$. As $\ell$ is a halving ray and $p$ an extreme point for the $k$-mutation which takes place when $p$ crosses the line defined by $q$ and $r$, we have that $k \leq \frac{n}{2} - 2$. Therefore, from Lemma 3 it follows that the number of crossings of $S$ decreases.

Lemma 3. For every pair of non-consecutive extreme points $p$ and $q$ of $S$, we can choose halving rays that cross in the interior of the convex hull of $S$.

Proof. Let $h$ be the line through $p$ and $q$. Then there is at least one open half plane $H$ defined by $h$ which contains at least $\lceil \frac{n-2}{2} \rceil$ points of $S$. So we can choose the two halving rays in such a way that their tails lie in $H$. Now suppose that the two halving rays do not cross in the interior of the convex hull of $S$. Then they split $S$ into three regions, two outer regions and one central region. In each outer region there are at least $\lfloor \frac{n-1}{2} \rfloor$ points, since they are supported by halving rays. In the central region there is at least the point which lies on the convex hull of $S$ between $p$ and $q$ and not in $H$. Finally, there are $p$ and $q$ themselves. All together we have $2 \cdot \lfloor \frac{n-1}{2} \rfloor + 1 + 2 \geq n + 1$ points, a contradiction, hence the lemma follows.

Observation 1. Using order type preserving projective transformations it can also be seen that a triangular convex hull can be obtained by projection along the halving ray. This is a rather common tool when working with order types, see e.g. [13]. However, we have decided to use a self-contained, planar approach.

We now have the ingredients to go for our first result, which seems to have been a common belief (see e.g. [10]) and for which evidence was provided by all configurations attaining $\overline{\text{cr}}(K_n)$ for $n \leq 17$, [2, 4].

Theorem 4. Any set $S$ of $n \geq 3$ points in the plane in general position attaining the rectilinear crossing number has precisely 3 extreme points, that is, a triangular convex hull.

Proof. For the sake of a contradiction, assume that $S$ is a set of points attaining the rectilinear crossing number and having more than 3 extreme points. Let $p$ and $q$ be two non-consecutive extreme points of $S$ and let $\ell_p$ and $\ell_q$ be their halving rays chosen according to Lemma 3. Let $s$ be a line parallel to the line $h$ through $p$ and $q$, such that $S$ entirely lies on one side of $s$ and $\ell_p, \ell_q$ are oriented towards $s$ (see Figure 3). Furthermore, let $s$ be placed arbitrarily close to $S$.

![Figure 3: Decreasing the number of crossings and the number of extreme points.](image-url)
Now move $p$ along $\ell_p$ until it reaches the intersection of $\ell_p$ and $s$: If a mutation occurs, we already reduce the number of crossings by Lemma 2. Then move $q$ along $\ell_q$ up to the intersection of $\ell_q$ and $s$. Note that, by Lemma 3, $\ell_p$ and $\ell_q$ do not cross in their heads; hence the movements of $p$ along $\ell_p$ and $q$ along $\ell_q$ do not interfere with each other.

After moving $p$ and $q$, all extreme points of $S$ between them changed to interior points. Hence at least one mutation happened, since $p$ and $q$ are non-consecutive, and therefore the number of crossings of $S$ decreased, which contradicts the optimality of $S$.

\[\square\]

Observation 2. If $S$ has 3 extreme points, from the proof of Theorem 4 it follows that we can keep moving the three extreme points of $S$ along their respective halving rays: If mutations occur, this further reduces the rectilinear crossing number. Thus, for an optimal set $S$ the three extreme points have to be `far away' in the following sense: For every extreme point $p$ of $S$, the cyclic sorted order of $S\setminus\{p\}$ around $p$ has to be the same as its sorted order in the direction orthogonal to the halving ray of $p$. (Otherwise another mutation would occur when we keep on moving $p$).

3 Lower bound for $(\leq k)$-edges

A $j$-edge, $0 \leq j \leq \left\lfloor \frac{n-2}{2} \right\rfloor$, is a segment spanned by the points $p,q \in S$ such that precisely $j$ points of $S$ lie in one open half space defined by the line through $p$ and $q$. In other words, a $j$-edge splits $S\setminus\{p,q\}$ into two subsets of cardinality $j$ and $n-2-j$, respectively. Note that here we consider non-oriented $j$-edges, i.e., the edge $pq$ equals the edge $qp$. We say that a $j$-edge is a halving edge if it splits the set as equally as possible, i.e., if $j = \frac{n-2}{2}$ when $n$ is even and if $j = \frac{n-3}{2}$ when $n$ is odd.

A $(\leq k)$-edge has at most $k$ points in this half space, that is, it is a $j$-edge for $0 \leq j \leq k$. We denote by $E_k(S)$ the number of $(\leq k)$-edges of $S$ and omit the set when it is clear from the context. Finally, $(E_0, \ldots, E_{\left\lfloor \frac{n-2}{2} \right\rfloor})$ is the $(\leq k)$-edge vector of $S$.

A $k$-set of $S$ is a set $S' \subset S$ of $k$ points that can be separated from $S\setminus S'$ by a line (hyperplane in general dimension). In dimension 2 there is a one-to-one relation between the numbers of $k$-sets and $(k-1)$-edges, since each of these objects can be derived from precisely two of its corresponding counterparts. Thus, in this paper we will solely use the notion of $j$-edges, although all the results can also be stated in terms of $k$-sets.

In the next lemma we study how the number of $j$-edges changes during a mutation.

Lemma 5. Let $k \leq \frac{n-3}{2}$. During a $k$-mutation, the number of $j$-edges changes in the following way: For $k < \frac{n-3}{2}$, the number of $k$-edges decreases by one and the number of $(k+1)$-edges increases by one. For $k = \frac{n-3}{2}$ everything remains unchanged.

Proof. We use the same notation as for the proof of Lemma 1. First observe that the only edges that change their property are the edges spanned by points $p_1$, $p_2$, and $p_3$. Let $k < \frac{n-3}{2}$. Before the mutation, $p_1p_2$ and $p_1p_3$ are $k$-edges, while $p_2p_3$ is a $(k+1)$-edge. After the mutation, the situation is reversed: $p_1p_2$ and $p_1p_3$ are $(k+1)$-edges while $p_2p_3$ is a $k$-edge. So in total we get one more $(k+1)$-edge and one less $k$-edge. For $k = \frac{n-3}{2}$ the two types of edges considered are halving edges before and after the mutation, that is, the number of halving edges does not change. \[\square\]
From Lemma 1 and Lemma 5 we get a relation between the number $\text{cr}(S)$ of rectilinear crossings of $S$ and the number of $j$-edges of $S$, denoted by $e_j$. An equivalent relation can be found in [19].

**Lemma 6.**

$$\text{cr}(S) + \sum_{j=0}^{\lfloor \frac{n-2}{2} \rfloor} j \cdot (n - j - 2) \cdot e_j = \frac{1}{8} \cdot (n^4 - 6n^3 + 11n^2 - 6n).$$

**Proof.** Looking for an expression of the form $\sum_j \alpha_j e_j$ that cancels the variation in the number of crossings during a mutation, we get the relation $\alpha_{j+1} = \alpha_j + n - 2j - 3$. The result corresponds to choosing $\alpha_0 = 0$. The right hand side of the equation can be easily derived from the convex set.

For the extremal case of $j$-edges, that is, halving edges, we can state a result similar to Theorem 4

**Theorem 7.** For any fixed $n \geq 3$, there exist point sets with a triangular convex hull that maximize the number of halving edges.

**Proof.** As observed in the proof of Lemma 2 when an extreme point $p$ is moved along a halving ray, only $k$-mutations with $k \leq \frac{n}{2} - 2$ can occur. Therefore, from Lemma 5 it follows that the number of halving lines cannot decrease. Then, we can proceed as in the proof of Theorem 4.

One might wonder whether we can obtain a stronger result similar to Theorem 4 stating that any point set maximizing the number of halving edges has to have a triangular convex hull. But there exist sets of 8 points with 4 extreme points bearing the maximum of 9 halving edges, see [5], and similar examples exist for larger $n$. Hence, the stated relation is tight in this sense. We leave as an open problem the existence of a constant $h$ such that any point set maximizing the number of halving edges has at most $h$ extreme points. We conjecture that such a constant exists, and the results for $n \leq 11$ suggest that $h = 4$ could be the tight bound.

Similar arguments as above can be used to prove the next result, which is our starting point for the lower bound of $(\leq k)$-edges:

**Lemma 8.** Let $S$ be a set of $n$ points with $h > 3$ extreme points and $(\leq k)$-edge vector $(E_0, \ldots, E_{\lfloor \frac{n-2}{2} \rfloor})$. Then there exists a set $S'$ of $n$ points with triangular convex hull and $(\leq k)$-edge vector $(E'_0, \ldots, E'_{\lfloor \frac{n-2}{2} \rfloor})$ with $E'_i \leq E_i$ for all $i = 0, \ldots, \lfloor \frac{n-2}{2} \rfloor$ (where at least one inequality is strict).

**Proof.** The proof follows the lines of the proof for Theorem 4 to obtain a set with only 3 extreme vertices. Observe that for all $k$-mutations which occur during this process it holds $k \leq \frac{n}{2} - 2$ because we are moving along halving rays. Thus by Lemma 5 every mutation decreases the number of $k$-edges by one and increases the number of $(k+1)$-edges by one. For the $(\leq k)$-edge vector this means that $E_k$ is decreased by one and the rest of the vector remains unchanged. The statement follows.

As a warm-up, we start with a really simple and geometric proof of the following bound, which has been independently shown in [1, 19] using circular sequences:
Theorem 9. Let $S$ be a set of $n$ points in the plane. The number of $(\leq k)$-edges of $S$ is at least $3\left(\frac{k+2}{2}\right)$ for $0 \leq k < \frac{n-2}{2}$. This bound is tight for $k \leq \left\lfloor \frac{n}{3} \right\rfloor - 1$.

Proof. By Lemma 8 we can assume that $S$ has a triangular convex hull, as otherwise we can find a point set with a strictly smaller $(\leq k)$-edge vector for which the theorem still has to hold. Let $p, q, r$ be the three extreme points of $S$.

By rotating a ray around each extreme point of $S$, we get exactly three 0-edges and six $j$-edges for every $1 \leq j < (n-2)/2$, all of them incident to $p, q$ or $r$. This gives a total of $3 + 6k$ $(\leq k)$-edges, which already proves the lower bound for $k = 1$. For $2 \leq k < \frac{n-2}{2}$ we will prove the lower bound by induction on $n$. The cases $n \leq 3$ are obvious and serve as an induction base. So for $n \geq 4$ consider $S_1 = S \setminus \{p, q, r\}$ where $n_1 = n - 3 \geq 1$ denotes the cardinality of $S_1$.

Observe that, since the convex hull of $S$ is a triangle, a $j$-edge of $S_1$ is either a $(j+1)$-edge or a $(j+2)$-edge of $S$. Therefore, if $2 \leq k < \frac{n-2}{2}$ we get

$$E_k(S) \geq E_{k-2}(S_1) + 3 + 6k \geq 3\left(\frac{k}{2}\right) + 3 + 6k = 3\left(\frac{k+2}{2}\right).$$

Finally, the example in [11] shows that the bound $3\left(\frac{j+2}{2}\right)$ is tight for $j \leq \left\lfloor \frac{n}{3} \right\rfloor - 1$. \hfill \ensuremath{\Box}

In view of the preceding proof, it is clear that in order to improve the bound for $k \geq \left\lfloor \frac{n}{3} \right\rfloor$ we need to show that a number of $j$-edges of $S_1$ are $(j+1)$-edges of $S$. This is going to be our next result, but first we need some preparation.

It is more convenient now to consider oriented $j$-edges: an oriented segment $pq$ is a $j$-edge of $S$ if there are exactly $j$ points of $S$ in the open half plane to the right of $pq$. Following [14], we rotate a directed line $\ell$ around points of the set $S$, counterclockwise, and in such a way that, when $\ell$ contains only one point, it has exactly $k$ points of $S$ on its right. We refer to this movement as a $k$-rotation. If the line rotates around a point $p$, the half-lines into which $p$ divides $\ell$ are the head and the tail of the line. Observe that, if during a $k$-rotation the line $\ell$ reaches a new point $q$ on its tail, then $qp$ is a $(k-1)$-edge and the $k$-rotation continues around $q$. On the other hand, if the new point $q$ appears on the head of the ray, then $pq$ is a $k$-edge and the $k$-rotation continues also around $q$. We recall that when a $k$-rotation of $2\pi$ is completed, all $k$-edges of $S$ have been found.

We denote by $\ell^+$ and $\ell^-$, respectively, the open and closed half-planes to the right of $\ell$ and, similarly, $\ell^{-}$ and $\ell^{+}$ will be the half-planes to the left of $\ell$.

Theorem 10. Let $S$ be a set of $n$ points in the plane in general position and let $T$ be a triangle containing $S$. If $\left\lfloor \frac{n}{3} \right\rfloor \leq k \leq \frac{n}{2} - 1$, then there exist at least $3k - n + 3$ $k$-edges of $S$ having to the right only one vertex of $T$.

Proof. Let $p, q$ and $r$ be the vertices of $T$ in counterclockwise order. Throughout this proof, we will refer to a $k$-edge and its supporting line synonymously. Moreover, edges having one vertex of $T$ on its right will be called good edges, and the rest will be said to be bad.

We start with the case of halving lines for $n$ even, which is straightforward. There are at least $n$ halving lines and exactly half of them are good (because each edge is a halving line in both orientations). Therefore, because $k = \frac{n}{2} - 1$, we have that $\frac{n}{2} = 3k - n + 3$. In the following, $k < \frac{n}{2} - 1$.

Since the number of $k$-edges is always at least $2k + 3$ (see [19]), if all $k$-edges are good the result is true. Therefore, without loss of generality, we can assume that there are bad edges
Figure 4: Proving Theorem 10: \( k \)-edges and their relation to the triangle \( T \).

having \( q \) and \( r \) on its right. Among them, let \( \ell_1 \) be the bad \( k \)-edge which intersects \( pq \) closest to \( q \). Now, we make a \( k \)-rotation of \( \ell_1 \) and distinguish two cases. For the whole proof refer to Figure 4.

Case 1. If a \( k \)-edge having \( p \) and \( r \) on its right is not found, then a good \( k \)-edge can be found for each of the \( k \) points to the right of \( \ell_1 \): if \( a \in \ell_1^+ \), consider a directed line through \( a \) and parallel to \( \ell_1 \) and rotate it around \( a \). Before rotating 180 degrees, a \( k \)-edge is found and it has to be good because there is no \( k \)-edge having \( p \) and \( r \) on its right. Therefore, because \( k \leq n - 3 \), it holds that \( k \geq 3k - n + 3 \) and the result follows.

Case 2. Let \( \ell_2 \) be the first \( k \)-edge we obtain from the rotation for which \( p \) and \( r \) lie on its right. Let \( H = S \cap \ell_2^+ \cap \ell_2^+ \) and denote by \( h \) the cardinality of \( H \). Observe that all \( k \)-edges between \( \ell_1 \) and \( \ell_2 \) we get during the rotation are good edges. Since points in \( H \) are necessarily encountered in the head of the ray during the \( k \)-rotation at least once, there is a good \( k \)-edge incident to each of them. Consider \( C_1 = S \cap \ell_1^+ \cap \ell_2^+ \) and denote by \( c_1 \) its cardinality. If \( c_1 = 0 \), then \( h = k \) and the result follows as in Case 1. Let \( \ell_3 \) be a \( k \)-edge tangent to \( C_1 \) at only one point and leaving \( C_1 \) on its left. Observe that \( \ell_3 \) could have \( r \) to its right and that it can be found by rotating a tangent to \( C_1 \) counterclockwise and, if a \( k \)-edge \( uv \) defined by two points of \( C_1 \) is found, proceeding with the rotation with \( v \) as new center (maybe repeatedly). Finally, let \( C_2 = S \cap \ell_1^+ \cap \ell_3^+ \) and \( \ell_4 \) be the common tangent to \( C_1 \) and \( C_2 \) leaving both sets to its left.

Now we want to bound the number of points in \( \ell_4^+ \). To this end, observe that \( k - h \leq c_1 \leq k - h + 2 \), depending on the number of points defining \( \ell_2 \) that belong to \( C_1 \). Therefore, if we denote by \( m \) the number of points in \( M = (S \cap \ell_4^+) \setminus (C_1 \cup C_2) \), then \( |S \cap \ell_4^+| \geq k + m + c_1 + 1 \) (start from \( \ell_3 \): it has \( k \) points to the right. In addition we have \( m + c_1 \) points plus a point not in \( C_1 \) defining \( \ell_3 \)). Therefore, \( |S \cap \ell_4^+| \leq n - k - m - c_1 - 1 \). Again we have to distinguish two cases:

Case 2a. \( c_1 \geq k - h + 1 \). In this case, \( |S \cap \ell_4^+| \leq n - 2k + h - m - 2 \). Therefore, if \( |S \cap \ell_4^+| > k \), then \( h > 3k - n + 2 + m \), implying \( h \geq 3k - n + 3 \) and thus the \( h \) good \( k \)-edges incident to points in \( H \) (see above) are sufficient to guarantee the result.

On the other hand, if there are at most \( k \) points to the right of \( \ell_4 \), we can rotate \( \ell_4 \)
around \(C_1\), clockwise, and find a \(k\)-edge \(\ell_5\) (which could be bad and which could also coincide with \(\ell_4\)). Observe that when rotating from \(\ell_4\) to \(\ell_5\) only points from \(M\) and \(C_2\) can be passed by the line and that one point spanning \(\ell_5\) belongs to either \(M\) or \(C_2\). Thus \(|C_2 \cap \ell_5^5| \geq k - |S \cap \ell_4^4| - m + 1 \geq 3k - n + 3 - h\).

We finally claim that for each point in \(C_2 \cap \ell_5^5\) we can find a good \(k\)-edge, which together with the \(h\) good edges from \(H\) settles Case 2a. To prove the claim let \(u \in C_2 \cap \ell_5^5\) and consider the half-cone with apex at \(u\), edges parallel to \(\ell_3\) and \(\ell_5\) and containing \(C_1\). Because \(\ell_5\) and \(\ell_3\) are \(k\)-edges, we can guarantee that if we rotate a line around \(u\) we find at least two \(k\)-edges, \(uv\) and \(wu\), and that at least one of them is good: Start from the line parallel to \(\ell_5\) which has less than \(k\) points to its right and more than \(k\) points to its left. Rotating counterclockwise around \(u\) until the line is parallel to \(\ell_3\) reverses the situation. Thus, during the rotation we first get an edge \(uv\) with \(k\) points to its right and then an edge \(wu\) with \(k\) points to its left. If \(r\) is to the left of \(uv\) then \(uv\) is the good \(k\)-edge for \(v\). Otherwise \(r\) has to be to the right of \(uw\) and thus \(wu\) is the good \(k\)-edge for \(v\). Finally observe that all good \(k\)-edges associated to points in \(C_2 \cap \ell_5^5\) in this last step are different from the good \(k\)-edges incident to points in \(H\) which were found in the first part of the \(k\)-rotation because the former ones have \(r\) to its left while the later ones have \(r\) to its right.

Case 2b. \(c_1 = k - h\). In this case, the arguments of Case 2a give \(3k - n + 2\) good \(k\)-edges and one more is needed. Observe that, in this case, the points defining \(\ell_2\) are to the left of \(\ell_1\). Therefore, the point \(t\) in the tail of the \(k\)-edge defining \(\ell_2\) has a good \(k\)-edge incident to it: Points to the left of \(\ell_1\) and defining \(k\)-edges are found during the \(k\)-rotation, and the first time they are found, they have to define a good \(k\)-edge (recall that \(\ell_2\) was the first bad edge). As \(t\) does not belong to \(H\), the good \(k\)-edge incident to \(t\) (having \(r\) to its right) was not counted previously.

\[\textbf{Theorem 11.}\quad \text{Let} \ S \ \text{be a set of} \ n \ \text{points in the plane in general position and let} \ E_k(S) \ \text{be the number of} \ (\leq k) \ \text{edges in} \ S. \ \text{For} \ 0 \leq k < \left\lfloor \frac{n - 2}{3} \right\rfloor \ \text{we have} \]

\[E_k(S) \geq 3 \left(\frac{k + 2}{2}\right) + \sum_{j=\left\lfloor \frac{k}{2} \right\rfloor}^{k} (3j - n + 3).\]

\[\text{Proof.}\quad \text{The proof goes by induction on} \ n. \ \text{Observe that Lemma 8 guarantees that it is sufficient to prove the result for sets with triangular convex hull. Let} \ p, q, r \ \text{be the vertices of the convex hull of} \ S \ \text{and let} \ S_1 = S \setminus \{p,q,r\}. \ \text{For} \ k \leq \left\lfloor \frac{n}{3} \right\rfloor - 1 \ \text{the result is already given by Theorem 9.} \]

If \(k \geq \left\lfloor \frac{n}{3} \right\rfloor + 1\) then

\[E_{k-2}(S_1) \geq 3 \left(\frac{k}{2}\right) + \sum_{j=\left\lfloor \frac{k}{2} \right\rfloor}^{k-2} (3j - (n - 3) + 3) = 3 \left(\frac{k}{2}\right) + \sum_{i=\left\lfloor \frac{k}{3} \right\rfloor}^{k-1} (3i - n + 3).\]

Furthermore, as in the proof of Theorem 9 we know that there are exactly \(3 + 6k\) \((\leq k)\)-edges of \(S\) adjacent to \(p, q\) and \(r\), so using Theorem 10 we conclude that

\[E_k(S) \geq E_{k-2}(S_1) + 3 + 6k + 3(k - 1) - (n - 3) + 3 \geq 3 \left(\frac{k + 2}{2}\right) + \sum_{j=\left\lfloor \frac{k}{3} \right\rfloor}^{k} (3j - n + 3).\]
For \( k = \lfloor \frac{n}{3} \rfloor \), \( E_{k-2}(S_1) \geq 3(k) \) and then
\[
E_k(S) \geq 3 \binom{k}{2} + 3 + 6k + 3(k-1) - (n-3) + 3 = 3 \left( \binom{k+2}{2} + 3 \left\lfloor \frac{n}{3} \right\rfloor \right) - n + 3.
\]

As a main consequence of Theorem 11, we can obtain a new lower bound for the rectilinear crossing number of the complete graph:

**Theorem 12.** For each positive integer \( n \),
\[
\overline{cr}(K_n) \geq \left( \frac{41}{108} + \varepsilon \right) \left( \frac{n}{4} \right) + O(n^3) \geq 0.379631 \left( \frac{n}{4} \right) + O(n^3).
\]

**Proof.** As shown in [19], the number of \((\leq k)\)-edges and the crossing number of \( K_n \) are strongly related. More precisely, if we denote by \( \overline{cr}(S) \) the number of crossings when the complete graph is drawn with set of vertices \( S \), then
\[
\overline{cr}(S) = \sum_{k<\left\lfloor \frac{n}{3} \right\rfloor} (n-2k-3) E_k(S) + O(n^3) \tag{1}
\]
Writing \( 3 \binom{k+2}{2} + \sum_{j=\left\lfloor \frac{n}{3} \right\rfloor}^{k} (3j - n + 3) = \hat{E}_k \), we get
\[
\overline{cr}(K_n) \geq \sum_{k<\left\lfloor \frac{n}{2} \right\rfloor} (n-2k-3) \hat{E}_k = \frac{41}{108} \left( \frac{n}{4} \right) + O(n^3).
\]

Now, we can slightly improve the lower bound by exploiting a bound for \((\leq k)\)-edges which is better than \( \hat{E}_k \) when \( k \) is close to \( \frac{n}{2} \): In [19] it is shown that
\[
E_k(S) \geq \left( \frac{n}{2} \right) - n \sqrt{n^2 - 2n - 4k(k+1)} = F_k.
\]

A straightforward computation shows that, for \( n \) large enough, \( F_k \geq \hat{E}_k \) if \( k \geq 0.4981n \).

Applying again Equation (1) we get
\[
\overline{cr}(K_n) \geq \sum_{k<\left\lfloor \frac{n}{2} \right\rfloor} (n-2k-3) \hat{E}_k + \sum_{k=0.4981n}^{n-2} (n-2k-3) (F_k - \hat{E}_k) + O(n^3) = \left( \frac{41}{108} + \varepsilon \right) \left( \frac{n}{4} \right) + O(n^3).
\]

In order to give an estimation for \( \varepsilon \), let \( t_0 = 0.4981 \) and observe that
\[
\sum_{k=t_0n}^{n-2} (n-2k-3) (F_k - \hat{E}_k) = n^3 \sum_{k=t_0n}^{n-2} \left( 1 - 2 \frac{k}{n} \right) \left( \frac{1}{3} + \frac{k}{n} - 3 \left( \frac{k}{n} \right)^2 - \sqrt{1 - 4 \left( \frac{k}{n} \right)^2} \right)
\]
\[
= n^4 \int_{t_0}^{1/2} \left( 1 - 2t \right) \left( \frac{1}{3} + t - 3t^2 - \sqrt{1 - 4t^2} \right) dt + O(n^3).
\]

Therefore,
\[
\varepsilon = 24 \int_{t_0}^{1/2} \left( 1 - 2t \right) \left( \frac{1}{3} + t - 3t^2 - \sqrt{1 - 4t^2} \right) dt \simeq 1.4 \cdot 10^{-6}.
\]
Table 1: Values and bounds of $h_n$ for $13 \leq n \leq 27$.

| $n$  | 13  | 14  | 15  | 16  | 17  | 18  | 19  | 20  | 21  | 22  | 23  | 24  | 25  | 26  | 27  |
|------|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|
| $h_n$ | 31  | 22  | 39  | 28  | 47  | 33  | 56  | 38  | 43  | 66  | 44  | 75  | 51  | 85  | 57  | 96  |

Observation 3. Using Theorem 11 and Lemma 6 it can be shown that the configurations of 19 and 21 points in [2] are optimal for the number of crossings: their $(\leq k)$-edge vectors are, respectively, $(3, 9, 18, 30, 45, 63, 86, 115, 171)$ and $(3, 9, 18, 30, 45, 63, 84, 111, 144, 210)$. Because they match the bound in Theorem 11 for $k < \frac{n-3}{2}$, we have that $\mathcal{C}(3, 19) = 1318$ and $\mathcal{C}(3, 21) = 2055$.

Observation 4. Let us recall that, for $n$ odd, $j$-edges with $j = \frac{n-3}{2}$ are halving edges. Let $h_n = \max_{S=\{n\}} |S| = \frac{n-2}{2}$ be the maximum number of halving lines that a set of $n$ points can have. In Table 1 we present a summary of the values of $h_n$ for $13 \leq n \leq 27$: the value $h_{14} = 22$ and the upper bound for $h_{16}$ were shown in [9], while the lower bound for $h_{16}$ appeared in [12]. The rest of the lower bounds come from the examples in [2] and the upper bounds can be derived applying Theorem 11 with $k = \lfloor \frac{n-2}{2} \rfloor - 1$, namely $h_n \leq \binom{n}{2} - E\lfloor \frac{n-2}{2} \rfloor - 1$.

4 Concluding Remarks

In this paper we have presented a new lower bound for the number of $(\leq k)$-edges of a set of $n$ points in the plane in general position. As a corollary of this, a new lower bound for the rectilinear crossing number of $K_n$ is obtained. The basis of the technique is a property about the structure of sets minimizing the number of $(\leq k)$-edges or the rectilinear crossing number: such sets have always a triangular convex hull.

There are still a host of open problems and conjectures about these and related questions, among which we emphasize the following:

- Prove that the new lower bound is optimal for some range of $k$. Based on computational experiments, we conjecture that the bound is optimal for $k \leq \lceil \frac{5n}{17} \rceil - 1$.
- Prove that all sets maximizing the number of halving lines have a convex hull with at most $h$ vertices. We conjecture that $h = 4$ is sufficient.
- Prove that sets minimizing the crossing number maximize the number of halving lines.
