Carnitine is a natural substance found in protein–rich foods. It is also synthesized in the liver, kidney, and several other tissues, and is excreted from the kidney if levels become excessive [1]. Carnitine forms free and high–energy ester bonds with short or long fatty acids, such as acylcarnitine. Free carnitine participates in fatty acid β–oxidation and energy production by transporting long–chain fatty acids from the cytoplasm to the mitochondria [2]. Further, free carnitine regulates the function of the mitochondrial respiratory chain and is capable of eliminating excess intracellular fatty acids in muscular and cardiac cells as acylcarnitine [2]. Therefore, acyl/free carnitine ratio in the serum or plasma is now widely used as a marker of renal function.

**Summary:** Background: Carnitine plays a pivotal role in energy synthesis through β-oxidation in mitochondria. Serum and tissue levels of free carnitine are significantly decreased in dialysis patients, whereas acylcarnitine levels are increased. However, the precise kinetics and fate of carnitine fractions in chronic kidney disease (CKD) patients who are not on dialysis have not been clarified. This study aims to determine the kinetics of serum carnitine fractions in patients who were not on dialysis.

**Methods:** Seventy-five CKD patients not on dialysis were recruited in this study. Serum and urinary carnitine fraction levels were measured to evaluate the kinetics and regulation of serum carnitine fractions. Carnitine fractions were measured by the enzymatic cycling method.

**Results:** Total and free serum carnitine levels did not change with progression of CKD, whereas acylcarnitine levels and the acyl/free carnitine ratio significantly increased. Serum acylcarnitine levels were inversely associated with estimated glomerular filtration rate ($r^2 = 0.239, p < 0.001$), but free carnitine levels were not. Serum free carnitine levels were positively associated with urinary free carnitine excretion ($r^2 = 0.214, p < 0.001$), but serum acylcarnitine levels were not. Multiple stepwise regression analysis revealed that urinary free carnitine excretion and blood urea nitrogen were independent determinants of serum free carnitine and acylcarnitine levels, respectively.

**Conclusions:** The present study demonstrated that serum acylcarnitine levels increased with renal dysfunction independent of urinary excretion levels. Serum free carnitine was not affected by renal function in CKD patients who were not on dialysis.

**Key words** free carnitine, acylcarnitine, CKD, renal excretion
tissue carnitine deficiency. Carnitine deficiency causes muscle weakness and cardiac hypertrophy in rodents and humans [3–5]. Since more than 60% of serum carnitine is eliminated from the blood by hemodialysis (HD) [6, 7], carnitine deficiency is often observed in patients with HD. It has been reported that HD–related loss of carnitine accelerates the progression of cardiovascular disease in uremic subjects with an increased acyl/free carnitine ratio [8].

Circulating carnitine is reported to be mainly distributed between two compartments, large and slow turnover (muscle), and small and rapid turnover (liver, kidney, and other tissues)[9]. In healthy subjects, carnitine is efficiently reabsorbed by the transporter organic cation/carnitine transporter (OCTN2) in proximal tubular cells located in the brush border of the proximal tubular cell and is tightly regulated. Since carnitine levels are reported to be maintained within the normal range in vegetarians, healthy subjects conserve carnitine through renal tubular reabsorption[9]. In kidney disorders such as Fanconi syndrome, severe carnitine deficiency is reported due to decreased reabsorption in the proximal tubular cells[10]. However, the concentration of carnitine levels in other chronic kidney disease (CKD) patients not on HD is controversial [11, 12]. The main pathological renal involvement in patients with CKD is mitochondria–rich tubular cell dysfunction; therefore, we speculate that carnitine deficiency in subjects with CKD could induce tubular cell damage, leading to the progression of renal dysfunction. However, the precise fate and kinetics of circulating and urinary carnitine fraction have not yet been examined in CKD patients who are not on HD. In this study we measured the carnitine fraction levels in serum and urine and assessed the correlation with renal function and CKD staging.

**METHODS**

**Patients**

CKD patients who were not on HD were recruited in Kurume University Hospital (56.1 ± 20.0 years old, 34 male and 41 female, diabetic nephropathy (n = 16), chronic glomerulonephritis (n = 28), membranous glomerulonephritis (n = 8), minimal–change nephrotic syndrome (n = 10), lupus nephritis (n = 3), hypertensive nephrosclerosis (n = 2), polycystic kidney disease (n = 1), interstitial nephritis (n = 1), unknown etiology (n = 6). The diagnosis of CKD and its staging were determined in line with the National Kidney Foundation Kidney Disease Outcome Quality Initiative guidelines [13]. Informed consent was obtained from all patients, and the study protocol was approved by the institutional ethics committees of Kurume University School of Medicine (Approval Number; 12078). This work was conducted in line with the Declaration of Helsinki and was registered with the University Hospital Medical Information Network clinical trial database (UMIN000010953).

**Data Collection**

Medical history was obtained by questionnaire. Body mass index was calculated as an index of the presence or absence of obesity. Blood pressure (BP) was measured in an upright sitting position using a standard sphygmomanometer. Vigorous physical activity and smoking were avoided for at least 30 minutes before BP measurement.

Fasting blood was drawn from the antecubital vein to determine serum albumin, hemoglobin, blood urea nitrogen (BUN), creatinine, uric acid, and lipids (total cholesterol, high–density lipoprotein (HDL)–cholesterol, low–density lipoprotein (LDL)–cholesterol, and triglycerides). Spot urine was collected for the determination of proteinuria (g/gCr) and carnitine fractions. HDL–cholesterol and LDL–cholesterol were measured at a commercially available laboratory (Daiichi Pure Chemicals Co., Ltd, Tokyo, Japan). The other chemistries were measured at a commercially available laboratory (Wako Pure Chemical Industries, Ltd, Osaka, Japan). Serum and urinary levels of total and free carnitine, and acylcarnitine were determined using an enzymatic cycling method [14]. Urinary carnitine/creatinine ratio was used as an adjusted urinary carnitine fraction level.

Estimated glomerular filtration rate (eGFR) was calculated using the following formula; eGFR = 0.741 × 175 × serum Cr−1.154 × age−0.203 × (0.742 if female) [15, 16].

**Statistical Analysis**

Results are presented as mean ± standard deviation. Univariate regression analysis was performed for determinants of serum and urinary free and acylcarnitine. Multiple stepwise regression analysis was performed to assess the independent determinants of serum level free and acylcarnitine. When we analyzed independent determinants of serum acylcarnitine, BUN was used as a marker of the renal function instead of serum creatinine and eGFR because BUN showed the strongest correlation with serum acylcarnitine. One–way analysis of variance (ANOVA) was used to compare the urinary and serum carnitine levels among CKD stages. If the data met the assumption of
homogeneity of variances, Tukey’s honestly significant difference post hoc test was performed. Statistical significance was defined as \( p < 0.05 \). All statistical analyzes were performed with SPSS version 20 software.

RESULTS

Demographic Data

Demographic data of the patients are presented in Table 1. Average serum levels of total, free, and acylcarnitine were 57.8 ± 17.4, 45.0 ± 13.5, and 12.8 ± 7.8 μmol/L, respectively. Acyl/free carnitine ratio was 0.30 ± 0.19.

Correlation between serum carnitine fraction levels and renal function

Serum acylcarnitine levels and acyl/free carnitine ratio were inversely correlated with eGFR (\( r^2 = 0.239, p < 0.001 \), \( r^2 = 0.290, p < 0.001 \), respectively), whereas total and free carnitine levels were not (Fig. 1A–D). CKD stage did not affect serum total and free carnitine levels (Fig. 2A and B). On the other hand, serum acylcarnitine levels and acyl/free carnitine ratio were significantly increased in patients with CKD stage G5 compared with those in CKD stages G1–3 (Fig. 2C and D).

Correlation between urinary carnitine fraction levels and renal function

Next we evaluated the relationship between urinary carnitine fraction levels and renal function in these patients. As shown in Fig. 3, urinary free carnitine and acylcarnitine levels were not associated with renal function (Fig. 3A and B). Further, there was no difference in either urinary carnitine fraction according to the CKD stages (Fig. 3C and D).

Independent determinants of serum free carnitine and acylcarnitine

Next we evaluated the independent determinants of serum free carnitine and acylcarnitine in these patients. Urinary free carnitine levels were positively associated with serum free carnitine (\( r^2 = 0.214, p < 0.001 \)) (Fig. 4A), and were an independent determinant of serum free carnitine (Table 2). In contrast, urinary acylcarnitine levels were not associated with serum acylcarnitine levels. Several variables such as sex, hemoglobin, eGFR, total cholesterol, and HDL–cholesterol were all inversely associated with serum acylcarnitine values, whereas BUN, serum creatinine,

and uric acid had a positive association. BUN was the sole independent determinant of serum acylcarnitine in these patients \( p < 0.001 \) (Fig. 4B) (Table 3).

**DISCUSSION**

The salient findings of the present study are as follows. First, serum total and free carnitine levels did not change with progression of CKD, whereas acylcarnitine and acyl/free carnitine ratio were significantly increased in patients with CKD stage G5. Second, urinary free carnitine values are an independent correlate of serum free carnitine in CKD patients. Third, renal dysfunction evaluated by BUN was an independent determinant of serum acylcarnitine; however, urinary acylcarnitine levels were not correlated with serum acylcarnitine in these patients. These observations suggest that serum free carnitine might be strictly regulated by urinary free carnitine excretion, but serum acylcarnitine might increase in uremic conditions independent of renal excretion.

It has been reported that serum carnitine levels increase significantly in patients with renal failure. Chen et al. showed that serum carnitine levels were higher in patients with kidney disease compared with healthy subjects [17]. Further, they reported that patients with oliguria showed a large increase in serum carnitine, and concluded that the clinical significance of increased carnitine in renal insufficiency might be analogous to that of BUN, serum creatinine, or uric acid [17]. However, they did not measure free carnitine and acylcarnitine separately and did not report the correlation between serum and urinary carnitine fractions. In this study, acylcarnitine levels, but not free carnitine levels, were positively correlated with renal function, and independently associated with BUN levels, thus, the main increased carnitine fraction in renal insufficiency might be acylcarnitine. Further, serum free carnitine values were positively associated with urinary free carnitine levels, in that urinary free carnitine was a sole independent determinant of serum free carnitine, suggesting that serum free carnitine levels might tightly be regulated by the OCTN2 carnitine transporter in proximal tubular cells, thereby maintaining circulating free carnitine levels even in CKD patients who are not on HD.

Acylcarnitine levels have been reported to be higher in patients with renal insufficiency due to its decreased excretion in urine. In our study, serum acylcarnitine values also increased according to renal dysfunction; however, serum and urinary acylcarnitine levels were not correlated. Therefore, serum acylcarnitine levels increase with renal insufficiency independent of renal dysfunction. From these findings, we

R²=0.149. eGFR=estimated glomerular filtration rate; UP/UCrea=urinary protein/urinary creatinine ratio; LDL=low-density lipoprotein; HDL=high-density lipoprotein; UFreeC/UCrea=urinary free carnitine/urinary creatinine ratio.
speculate that some uremic toxins or mitochondrial dysfunction that results from renal dysfunction might cause the accumulation of acylcarnitine in serum in CKD patients. Since long-chain acylcarnitine in the serum has been reported, from metabolome analysis, to be a marker of cardiovascular death in HD patients [18], evaluating serum acylcarnitine levels might be valuable in maintaining the patient’s quality of life.

In this study, the acyl/free carnitine ratio also increased in association with the progression of renal dysfunction. A higher acyl/free carnitine ratio reflects tissue carnitine deficiency and decreased energy synthesis in mitochondria. In addition, it is associated with increased cardiac event rates in patients with heart failure [19]. Therefore, a higher acyl/free carnitine ratio might reflect carnitine deficiency in tissue and, consequently, may be involved in the development of cardiovascular disease in patients with CKD.

A recent study reported a close association between the serum acylcarnitine profile and non-alcoholic fatty liver disease (NAFLD) and NAFLD–related hepatocellular carcinoma [20]. Further, serum C16–acylcarnitine levels were affected by lung cancer [21]. Although we did not measure the serum acylcarnitine profile in this study, an examination of long-chain acylcarnitine might be valuable for evaluating the prognosis of patients with CKD.

Serum free carnitine levels less than 20 μmol/L are a criterion for carnitine deficiency. However, in our study, serum free carnitine levels in almost all patients were over 20 μmol/L, which differed from patients who underwent HD. Therefore, the evaluation of tissue carnitine levels, such as in red blood cells, might be useful to understand intracellular carnitine metabolism.

In conclusion, the present study demonstrates that serum levels of acylcarnitine increased according to the progression of CKD independent of urinary acyl-
