We provide a general framework to describe cooling of a micromechanical oscillator to its quantum ground state by means of radiation-pressure coupling with a driven optical cavity. We apply it to two experimentally realized schemes, back-action cooling via a detuned cavity and cold-damping quantum-feedback cooling, and we determine the ultimate quantum limits of both schemes for the full parameter range of a stable cavity. While both allow to reach the oscillator’s quantum ground state, we find that back-action cooling is more efficient in the good cavity limit, i.e. when the cavity bandwidth is smaller than the mechanical frequency, while cold damping is more suitable for the bad cavity limit. The results of previous treatments are recovered as limiting cases of specific parameter regimes.

INTRODUCTION

Cooling of mechanical resonators close to their quantum ground state has become an important topic for various fields of physics, such as ultra-high precision measurements, the detection of gravitational waves, and the study of the transition between classical and quantum behavior of a mechanical system. It is also a prerequisite for any possible use of optomechanical systems for quantum information processing. Recently, various experiments have demonstrated significant cooling of the vibrational mode of a mechanical resonator coupled to an optical cavity. In these experiments cooling has been achieved by exploiting in two different ways the radiation-pressure interaction between a mechanical mode and the intra-cavity field: i) by back-action, or self-cooling, in which the off-resonant operation of the cavity results in a retarded back action on the mechanical system and hence in a “self”-modification of its dynamics; ii) by cold-damping quantum feedback, where the oscillator position is measured through a phase-sensitive detection of the cavity output and the resulting photocurrent is used for a real-time correction of the dynamics.

We generalize and extend the previous treatments of these schemes to the full parameter range of a stable cavity by deriving the quantum steady state of the micromechanical oscillator in a linearized quantum Langevin equation (QLE) approach. Comparing the two schemes we find that back-action cooling is more efficient in the good cavity limit, i.e. when the cavity bandwidth is smaller than the mechanical frequency, while cold damping is more suitable in the opposite limit of a bad cavity. We also show that, contrary to common belief, the feedback gain in cold-damping schemes is necessarily bounded by an upper limit to achieve quantum ground-state cooling.

The paper is organized as follows. In Section II we describe the dynamics of the system in terms of linearized quantum Langevin equations. In Sec. III and IV we evaluate the steady-state energy of the mechanical oscillator for the two cases of back-action cooling with a detuned cavity and cold-damping feedback cooling. In Section V we conclude by comparing in detail the two cooling schemes.

QUANTUM LANGEVIN EQUATIONS FOR THE SYSTEM

We consider a driven optical cavity coupled by radiation pressure to a micromechanical oscillator. The typical experimental configuration is a Fabry-Perot cavity with one mirror much lighter than the other (see e.g. [7, 8, 9, 10, 11, 12, 16]), but our treatment applies to other configurations such as the silica toroidal microcavity of Refs. [13, 22]. Radiation pressure typically excites several mechanical degrees of freedom of the system with different resonant frequencies. However, a single mechanical mode can be considered when a bandpass filter in the detection scheme is used and coupling between the different vibrational modes can be neglected. The Hamiltonian of the system reads

\[ H = \hbar \omega_c a^\dagger a + \frac{1}{2} \hbar \omega_m (p^2 + q^2) - \hbar G_0 a^\dagger a q + i\hbar E(a^\dagger e^{-i\omega t} - a e^{i\omega t}). \]  (1)

The first term describes the energy of the cavity mode, with lowering operator \( [a, a^\dagger] = 1 \), cavity frequency \( \omega_c \) and decay rate \( \kappa \). The second term gives the energy of the mechanical mode, modeled as harmonic os-
cillator at frequency \( \omega_m \) and described by dimensionless position and momentum operators \( q \) and \( p \) (\( \{q, p\} = i \)). The third term is the radiation-pressure coupling of rate \( G_0 = (\omega_c/L)\sqrt{\hbar/m\omega_m} \), where \( m \) is the effective mass of the mechanical mode \( 24 \), and \( L \) is an effective length that depends upon the cavity geometry: it coincides with the cavity length in the Fabry-Perot case, and with the toroid radius in the case of Refs. \( 13, 22 \). The last term describes the input driving by a laser with frequency \( \omega_0 \), where \( E \) is related to the input laser power \( P \) by \( |E| = \sqrt{2P}/|\hbar\omega_0| \). One can adopt the single cavity mode description of Eq. (1) as long as one drives only one cavity mode and the mechanical frequency \( \omega_m \) is much smaller than the cavity free spectral range \( FSR \sim c/L \). In this case, scattering of photons from the driven mode into other cavity modes is negligible \( 22 \).

The dynamics are also determined by the fluctuation-dissipation processes affecting both the optical and the mechanical mode. They can be taken into account in a fully consistent way \( 24 \) by considering the following set of nonlinear QLE, written in the interaction picture with respect to \( \hbar\omega_0 t \)

\[
\begin{align*}
\dot{q} &= \omega_m p, \\
\dot{p} &= -\omega_m q - \gamma_m p + G_0 a^\dagger a + \xi, \\
\dot{a} &= -(\kappa + i\Delta_0)a + iG_0aq + E + \sqrt{2\kappa}a^\dagger, 
\end{align*}
\]

(2a)

(2b)

(2c)

where \( \Delta_0 = \omega_c - \omega_0 \). The mechanical mode is affected by a viscous force with damping rate \( \gamma_m \) and by a Brownian stochastic force with zero mean value \( \xi \), that obeys the correlation function \( 24, 27 \)

\[
\langle \xi(t)\xi(t') \rangle = \frac{\gamma_m}{\omega_m} \int \frac{d\omega}{2\pi} e^{-\omega(t-t')} \left[ \coth \left( \frac{\hbar\omega}{2k_B T} \right) + 1 \right],
\]

(3)

where \( k_B \) is the Boltzmann constant and \( T \) is the temperature of the reservoir of the micromechanical oscillator. The Brownian noise \( \xi(t) \) is a Gaussian quantum stochastic process and its non-Markovian nature (neither its correlation function nor its commutator are proportional to a Dirac delta) guarantees that the QLE of Eqs. (2) preserve the correct commutation relations between operators during the time evolution \( 24 \). The cavity mode amplitude instead decays at the rate \( \kappa \) and is affected by the vacuum radiation input noise \( a^\dagger(t) \), whose correlation functions are given by

\[
\langle a^\dagger(t)a^\dagger(t') \rangle = [N(\omega_c) + 1] \delta(t-t'),
\]

(4)

and

\[
\langle a(t)a(t') \rangle = N(\omega_c)\delta(t-t'),
\]

(5)

where \( N(\omega_c) = (\exp\{\hbar\omega_c/k_B T\} - 1)^{-1} \) is the equilibrium mean thermal photon number. At optical frequencies \( \hbar\omega_c/k_B T \gg 1 \) and therefore \( N(\omega_c) \geq 0 \), so that only the correlation function of Eq. (4) is relevant.

Cooling of the mechanical oscillator by radiation pressure can be described in thermodynamical terms in the following way. Radiation pressure couples the oscillator to the optical cavity mode, which behaves as an effective additional reservoir for the oscillator when the cavity is appropriately detuned. As a consequence, the effective temperature of the mechanical mode will be intermediate between the initial reservoir temperature and that of the effective optical reservoir, which is in practice equal to zero due to the condition \( N(\omega) \geq 0 \). Therefore one approaches the mechanical ground state when the coupling rate to the optical reservoir is much larger than the damping rate \( \gamma_m \) which gives the coupling to the initial reservoir. This explains why significant cooling is obtained when radiation pressure coupling is strong. It is realized when the coupling \( G_0 \) is large, but is more easily achieved when the intracavity field is very intense, i.e., for high-finesse cavities and enough driving power. In this limit (and if the system is stable) the system is characterized by a semiclassical steady state with the cavity mode in a coherent state with amplitude \( \alpha_s \) (\( |\alpha_s| \gg 1 \)), and a new equilibrium position for the oscillator, displaced by \( q_s \). The parameters \( \alpha_s \) and \( q_s \) are the solutions of the nonlinear algebraic equations obtained by factorizing Eqs. (2) and setting the time derivatives to zero. They are given by

\[
q_s = \frac{G_0|\alpha_s|^2}{\omega_m},
\]

(6)

\[
\alpha_s = \frac{E}{\kappa + i\Delta},
\]

(7)

where the latter equation is in fact the nonlinear equation determining \( \alpha_s \), since the effective cavity detuning \( \Delta \), including radiation pressure effects, is given by

\[
\Delta = \Delta_0 - \frac{G_0^2|\alpha_s|^2}{\omega_m^2}.
\]

(8)

Rewriting each Heisenberg operator of Eqs. (2) as the c-number steady state value plus an additional fluctuation operator with zero mean value, one gets the exact QLE for the fluctuations

\[
\begin{align*}
\delta\dot{q} &= \omega_m \delta p, \\
\delta\dot{p} &= -\omega_m \delta q - \gamma_m \delta p + G_0 (\alpha_s \delta a^\dagger + \alpha^\dagger_s \delta a) + \delta a^\dagger \delta a + \xi, \\
\delta\dot{a} &= -(\kappa + i\Delta)\delta a + iG_0 (\alpha_s + \delta a) \delta q + \sqrt{2\kappa}a^\dagger, 
\end{align*}
\]

(9)

We have assumed \( |\alpha_s| \gg 1 \), therefore one can safely neglect the nonlinear terms \( \delta a^\dagger \delta a \) and \( \delta a \delta \delta \) in the equations above and obtains the linearized QLE

\[
\begin{align*}
\delta\dot{q} &= \omega_m \delta p, \\
\delta\dot{p} &= -\omega_m \delta q - \gamma_m \delta p + G\delta X + \xi, \\
\delta\dot{X} &= -\kappa \delta X + \Delta \delta Y + \sqrt{2\kappa}X^\dagger, \\
\delta\dot{Y} &= -\kappa \delta Y - \Delta \delta X + G\delta q + \sqrt{2\kappa}Y^\dagger.
\end{align*}
\]

(10a)

(10b)

(10c)

(10d)
Here we have chosen the phase reference of the cavity field so that $\alpha_s$ is real and positive, and we have defined the cavity field quadratures $\delta X \equiv \alpha a + \delta a^+ / \sqrt{2}$ and $\delta Y \equiv \alpha a^+ - \delta a / \sqrt{2}$, and the corresponding Hermitian input noise operators $X^{in} \equiv (a^{in} + a^{in+}) / \sqrt{2}$ and $Y^{in} \equiv (a^{in} - a^{in+}) / \sqrt{2}$. The linearized QLE show that the mechanical mode is coupled to the cavity mode quadrature fluctuations by the effective optomechanical coupling

$$G = G_0 \alpha_s \sqrt{2} = \frac{2\omega_c}{L} \frac{P_H}{m \omega_m \omega_0 (\kappa^2 + \Delta^2)}, \quad (11)$$

which can be made very large by increasing the intracavity amplitude $\alpha_s$. Notice that together with the condition $\omega_m \ll c/L$, which is required for the single cavity mode description, $|\alpha_s| \gg 1$ is the only assumption required by the present approach. We shall see below that, thanks to this fact, the present approach provides a generalization of previous treatments of back-action cooling, such as the semiclassical treatment of Ref. [17] and the perturbation treatments of [28, 29].

**DETUNING-INDUCED BACK-ACTION COOLING**

We have to evaluate the mean energy of the oscillator in the steady state

$$U = \frac{\hbar \omega_m}{2} \left[ \langle \delta q^2 \rangle + \langle \delta p^2 \rangle \right] = \hbar \omega_m \left( n_{\text{eff}} + \frac{1}{2} \right), \quad (12)$$

and to see if and when it approaches the ground-state value $\hbar \omega_m/2$. This is equivalent to determine the conditions under which $\langle \delta q^2 \rangle \approx \langle \delta p^2 \rangle \approx 1/2$. The two oscillator variances $\langle \delta q^2 \rangle$ and $\langle \delta p^2 \rangle$ can be obtained by solving Eqs. (11) in the frequency domain and integrating the corresponding fluctuation spectrum. One gets

$$\langle \delta q^2 \rangle = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} S_q(\omega), \quad \langle \delta p^2 \rangle = \int_{-\infty}^{\infty} \frac{d\omega}{2\pi} \omega^2 S_p(\omega), \quad (13)$$

where the position spectrum is given by

$$S_q(\omega) = |\chi_{\text{eff}}^q(\omega)|^2 [S_{th}(\omega) + S_{rp}(\omega, \Delta)], \quad (14)$$

where

$$S_{th}(\omega) = \frac{\gamma_m \omega_m}{\omega_m} \coth \left( \frac{\hbar \omega}{2 k_B T} \right) \quad (15)$$

is the thermal noise spectrum,

$$S_{rp}(\omega, \Delta) = \frac{G^2 \kappa [\Delta^2 + \kappa^2 + \omega^2]}{[\kappa^2 + (\omega - \Delta)^2] [\kappa^2 + (\omega + \Delta)^2]} \quad (16)$$

is the radiation pressure noise spectrum, and

$$\chi_{\text{eff}}^q(\omega) = \omega_m \left[ \omega_m^2 - \omega^2 - i \omega \gamma_m - \frac{G^2 \omega_m}{(\kappa - i \omega)^2 + \Delta^2} \right]^{-1} \quad (17)$$

is the effective susceptibility of the oscillator, modified by radiation pressure. The latter can be read as the susceptibility of an oscillator with effective resonance frequency and damping rate given by

$$\omega_{m_{\text{eff}}}^2(\omega) = \left[ \omega_m^2 - \frac{G^2 \Delta \omega_m [(\omega_0^2 - \omega^2 + \Delta^2)]}{[\kappa^2 + (\omega - \Delta)^2] [\kappa^2 + (\omega + \Delta)^2]} \right]^{\frac{1}{2}} \quad (18)$$

$$\gamma_{m_{\text{eff}}}^2(\omega) = \gamma_m + \frac{2 G^2 \Delta \omega_m \kappa}{[\kappa^2 + (\omega - \Delta)^2] [\kappa^2 + (\omega + \Delta)^2]} \quad (19)$$

The modification of the mechanical frequency due to radiation pressure shown by Eq. (18) is the so-called “optical spring effect”, which may lead to significant frequency shifts in the case of low-frequency oscillators, such as pendulum modes of suspended mirrors [14]. In the case of high resonance frequencies, such as those of Refs. [3, 11, 13] where $\omega_m \gtrsim 1$ MHz, the optical spring term in Eq. (18) does not significantly alter the frequency, even for large intracavity power. Here, we shall only consider numerical examples with large $\omega_m$, where the

![Figure 1](image-url)

**FIG. 1:** Plot of the effective mechanical frequency of Eq. (18) (a) and of the effective mechanical damping of Eq. (19) (b) versus frequency. Parameter values are $\omega_m/2\pi = 10$ MHz, $\gamma_m/2\pi = 100$ Hz, $\Delta = \omega_m$, $\kappa = 0.2 \omega_m$ and $G = 0.2 \omega_m$ (dashed line), $G = 0.3 \omega_m$ (dotted line) and $G = 0.4 \omega_m$ (full line), which we shall see later correspond to an optimal cooling regime.
frequency is practically unchanged \(\omega_{m}^{eff}(\omega) \simeq \omega_m\), see Fig. 1). In fact, ground state cooling \(n_{eff} < 1\) can be approached only if the initial mean thermal excitation number \(\bar{n} = (\exp\{\hbar \omega_m/k_B T\} - 1)^{-1}\) is not prohibitively large, and this is possible, even at cryogenic temperatures, only if \(\omega_m\) is sufficiently large. For positive \(\Delta\) and for large enough \(G\) the effective mechanical damping is instead significantly increased (see Fig. 1). This increase is at the basis of the cooling process. In fact, the mechanical susceptibility at resonance is inversely proportional to damping and it is therefore significantly suppressed by radiation pressure. As a consequence, the oscillator is much less affected by thermal noise and this means cooling as long as the radiation-pressure noise contribution \(S_{rp}(\omega, \Delta)\) remains small compared to thermal noise term \(S_{th}(\omega)\), which is verified for not too large \(G\).

Let us now determine the oscillator mean energy. The system reaches a steady state only if it is stable and this is satisfied when all the poles of the effective susceptibility \(\chi_{eff}^{\Delta}\) lie in the lower complex half-plane. By applying the Routh-Hurwitz criterion \[30\], we get the following two nontrivial stability conditions in the detuned-cavity case:

\[
s_1 = 2\gamma_m \kappa \left\{ \left[ \kappa^2 + (\omega_m - \Delta)^2 \right] \left[ \kappa^2 + (\omega_m + \Delta)^2 \right] + \gamma_m \left[ (\gamma_m + 2\kappa) (\kappa^2 + \Delta^2) + 2\kappa \omega_m^2 \right] \right\} + \Delta \omega_m G^2 (\gamma_m + 2\kappa)^2 > 0, \tag{20a}
\]

\[
s_2 = \omega_m (\kappa^2 + \Delta^2) - G^2 \Delta > 0. \tag{20b}
\]

When the stability conditions are satisfied, the integrals of Eq. (13) for the two variances can be solved exactly. However, it is reasonable to simplify the thermal noise contribution in Eqs. (13). In fact \(k_B T/\hbar \simeq 10^{11} \text{s}^{-1}\) even at cryogenic temperatures and therefore is always much larger than all the other parameters. At these high values of \(\omega\) the position spectrum is negligible and therefore one can safely approximate in the integral

\[
\frac{\gamma_m \omega}{\omega_m} \coth \left( \frac{\hbar \omega}{2 k_B T} \right) \simeq \gamma_m 2 k_B T / \hbar \omega_m \simeq \gamma_m (2\bar{n} + 1). \tag{21}
\]

Performing the integrals, one gets the final expressions for the two variances, which are given by

\[
\langle \delta q^2 \rangle = \frac{1}{2} + b_q + d_q \bar{n}, \tag{22}
\]

\[
\langle \delta p^2 \rangle = \frac{1}{2} + b_p + d_p \bar{n}, \tag{23}
\]

\[
\begin{align*}
\frac{b_q}{d_q} & = [s_1]^{-1} G^2 \kappa \left\{ \Delta^2 (\gamma_m + \kappa) + \kappa (\gamma_m \kappa + \kappa^2 + \omega_m^2) - \Delta \omega_m (\gamma_m + 2\kappa) \right\}, \tag{24} \\
\frac{b_p}{d_p} & = 1 - [s_1]^{-1} 2 G^2 \kappa \omega_m \Delta (\gamma_m + 2\kappa), \tag{25} \\
\frac{b_q}{d_q} & = [s_1 s_2]^{-1} G^2 \left\{ 2 \kappa (\Delta^2 + \gamma_m^2) \left( \Delta^2 + (\gamma_m + \kappa)^2 \right) (\kappa \omega_m + \gamma_m \Delta) \\
&+ \omega_m^2 (\gamma_m + \kappa) (\omega_m - 2\Delta) + \Delta G^2 \omega_m (\gamma_m + 2\kappa) [\Delta \gamma_m - \kappa (\omega_m - 2\Delta)] \right\}, \tag{26} \\
\frac{b_p}{d_q} & = 1 + [s_1 s_2]^{-1} G^2 [s_1 - 2\gamma_m \kappa \omega_m (\omega_m^2 + 2\gamma_m \kappa + \Delta^2) - 4\kappa^2 \omega_m^2 (\Delta^2 + \kappa^2)]. \tag{27}
\end{align*}
\]

At the ground state both variances are equal to 1/2 and therefore realizing ground state cooling means achieving \(b_q, b_p, d_q, d_p \to 0\). Notice that in general \(\langle \delta q^2 \rangle \neq \langle \delta p^2 \rangle\), that is, one does not have energy equipartition, as it is already shown by the general expression of Eq. (13). This means that in the generic case, the steady state of the system is not, strictly speaking, a thermal equilibrium state and this prevents to derive from here an univocally defined temperature. With this respect, Eq. (12) provides a definition of the effective mean excitation number \(n_{eff}\) from which one can only define an effective temperature as \(T_{eff} = \hbar \omega_m / [k_B \ln (1 + 1/n_{eff})]\). However, in order to get to the quantum ground state, both variances have to tend to 1/2 and therefore energy equipartition has to be satisfied in the optimal regime close to the ground state.

In order to have an intuitive picture and to facilitate the comparison with the recent perturbation treatments of Refs. \[28, 29\], we consider the expressions of the variances in some limiting case of experimental interest.

It is convenient to introduce the rates \[29\]

\[
A_{\pm} = \frac{G^2 \kappa}{2 \left[ \kappa^2 + (\Delta \pm \omega_m)^2 \right]}, \tag{28}
\]

which define the rates at which laser photons are scattered by the moving oscillator simultaneously with the
absorption (Stokes, $A_+$) or emission (anti-Stokes, $A_-$) of the oscillator vibrational phonons. For $\Delta > 0$ one has $A_- > A_+$ and a net laser cooling rate

$$\Gamma = A_- - A_+ > 0$$

can be defined, giving the rate at which mechanical energy is taken away by the leaking cavity. As a consequence, the total mechanical damping rate is given by $\gamma_m + \Gamma$, which is consistent with the expression of the effective (frequency-dependent) damping rate of Eq. (19): in fact, it is easy to check that

$$\gamma_m^{\text{eff}}(\omega = \omega_m) = \gamma_m + \Gamma. \quad (29)$$

As discussed in the preceding section, ground-state cooling is achievable when $\gamma_m$, the coupling rate with the thermal reservoir, is significantly smaller than $\Gamma$, which represents the coupling rate of the mechanical oscillator with the effective reservoir provided by the damped cavity mode. For small $\gamma_m$ the above expressions simplify to

$$\langle \delta p^2 \rangle = \frac{1}{\gamma_m + \Gamma} \left\{ \frac{A_+ + A_-}{2} + \gamma_m \bar{n} \left( 1 + \frac{\Gamma}{2\kappa} \right) \right\}, \quad (30)$$

$$\langle \delta q^2 \rangle = \frac{1}{\gamma_m + \Gamma} \left\{ a \frac{A_+ + A_-}{2} + \gamma_m \bar{n} \left( 1 + \frac{\Gamma}{2\kappa} b \right) \right\}, \quad (31)$$

where we have defined the coefficients

$$a = \frac{\kappa^2 + \Delta^2 + \eta_\Delta \omega_m^2}{\eta_\Delta (\kappa^2 + \Delta^2 + \omega_m^2)}, \quad (32)$$

$$b = \frac{2 (\Delta^2 - \kappa^2) - \omega_m^2}{\kappa^2 + \Delta^2}, \quad (33)$$

$$\eta_\Delta = 1 - \frac{G^2 \Delta}{\omega_m (\kappa^2 + \Delta^2)}. \quad (34)$$

Note that for positive $\Delta$, $0 < \eta_\Delta < 1$ due to the stability condition of Eq. (20b). Eqs. (30) and (31) provide a generalization of the results of Ref. [28, 29], which are reproduced if we take $\omega_m \gg \bar{n} \gamma_m, G$ and $\kappa \gg \gamma_m, G$ (assumed in Refs. [28, 29]) in Eqs. (32) and (33). In these limits $a, \eta_\Delta \to 1, \Gamma/\kappa \to 0$ and therefore

$$\langle \delta p^2 \rangle \simeq \langle \delta q^2 \rangle = n_{\text{eff}} + 1/2, \quad (35)$$

where

$$n_{\text{eff}} = \frac{\gamma_m \bar{n} + A_+}{\gamma_m + \Gamma} \quad (36)$$

is the basic result of Ref. [28] (see Eq. (9)) and Ref. [29] (see Eq. (5) and its derivation). This result has been also obtained in Ref. [31] through an approximate treatment of the exact integrals of Eq. (19).

The approximate expression of Eq. (36) suggests how the system parameters can be chosen in order to minimize the oscillator energy close to the ground-state value.

In order to reach the condition $n_{\text{eff}} < 1$ one needs a large $\Gamma/\gamma_m$ while keeping $A_+ / \Gamma$ small. This is done by matching $\Delta = \omega_m$, which optimizes the energy transfer from the mechanical mode to the anti-Stokes sideband. Further optimization requires a large value of $G$, which is however constrained by the stability condition $\eta_\Delta > 0$. When $\eta_\Delta \to 0$, $\langle \delta q^2 \rangle$ becomes too large, while the ground state, where $\langle \delta q^2 \rangle = 1/2$, is approached for $\eta_\Delta \sim 1$ (see Eq. (31)). Finally the optimal ratio $\kappa/\omega_m$ is determined by the fact that the laser-cooling rate $\Gamma$ has to be large but still smaller than $\kappa$ because the cavity response time $\sim \kappa^{-1}$ has to be remain shorter than that of the oscillator $\sim \Gamma^{-1}$. We find that, within a set of experimentally achievable parameters, the best cooling regime ($n_{\text{eff}} \approx 0.1$), is obtained in the good cavity limit condition $\kappa/\omega_m \ll 0.2$ (see Fig. 2), which is close to the value of $1/\sqrt{32}$ suggested in [29].

![Figure 2](image-url)

**FIG. 2.** (Color online) a) Effective mean vibrational number $n_{\text{eff}}$ versus $\Delta/\omega_m$ and $\kappa/\omega_m$ around the optimal ground-state cooling regime for $\omega_m / 2\pi = 10$ MHz, $\gamma_m / 2\pi = 100$ Hz, $m = 250$ ng, a cavity of length $L = 0.5$ mm driven by a laser with power $P = 50$ mW, and wavelength 1064 nm. The oscillator reservoir temperature is $T = 0.6$ K, corresponding to $\bar{n} \approx 1250$. The minimum value $n_{\text{eff}} \approx 0.1$ corresponds to an effective temperature $T_{\text{eff}} \approx 0.2$ mK. (b) Effective mean vibrational number $n_{\text{eff}}$ versus $\kappa/\omega_m$ and the normalized power $P/P_0$. ($P_0 = 50$ mW) at the fixed, optimal value for the detuning, $\Delta = \omega_m$. The other parameters are the same as in (a).
GROUND-STATE COOLING WITH COLD DAMPING

An alternative way of cooling the oscillator by over-damping, proposed in [14] and experimentally realized in [10, 12, 13], is to use quantum feedback and specifically cold damping [20, 21, 32]. This technique is based on the application of a negative derivative feedback, which increases the damping of the system without increasing the thermal noise. The oscillator position is measured by means of a phase-sensitive detection of the cavity output, which is then fed back to the oscillator by applying a force whose intensity is proportional to the time derivative of the output signal, and therefore to the oscillator velocity. One measures the phase quadrature \( Y \), whose Fourier transform, according to Eqs. (10), is given by

\[
\delta Y(\omega) = \frac{G(\kappa - i\omega)}{(\kappa - i\omega)^2 + \Delta^2} \delta q(\omega) + \text{noise terms.} \tag{37}
\]

This shows that the highest sensitivity for position measurements is achieved for a resonant cavity, \( \Delta = 0 \) and in the large cavity bandwidth limit \( \kappa \gg \omega_m, \gamma_m \), i.e., when the cavity mode adiabatically follows the oscillator dynamics \( \delta Y(\omega) \simeq (G/\kappa) \delta q(\omega) \). Therefore the QLE for the cold-damping scheme coincide with those of Eqs. (10) with \( \Delta = 0 \), but with an additional feedback force

\[
\begin{align*}
\delta \dot{q} &= \omega_m \delta p, \tag{38a} \\
\delta \dot{p} &= -\omega_m \delta q - \gamma_m \delta p + G \delta X + \xi, \tag{38b} \\
\delta \dot{X} &= -\kappa \delta X + \sqrt{2\kappa} \delta X^\text{in}, \tag{38c} \\
\delta \dot{Y} &= -\kappa \delta Y + G \delta q + \sqrt{2\kappa} \delta Y^\text{in}. \tag{38d}
\end{align*}
\]

In Eq. (35) \( g(t) \) is a causal kernel, proportional to a derivative of a Dirac delta in the ideal derivative feedback limit, and \( \delta Y^\text{est}(s) \) is the estimated intra-cavity phase quadrature that is obtained from the measurement of the output quadrature \( Y^\text{out}(t) \) as follows. The usual input-output relation

\[
\delta Y^\text{out}(t) = \sqrt{2\kappa} \delta Y(t) - Y^\text{in}(t) \tag{39}
\]

can be generalized to the case of a non-unit detection efficiency, by modeling a detector with quantum efficiency \( \eta \) with an ideal detector preceded by a beam splitter with transmissivity \( \sqrt{\eta} \), hence mixing the incident field with an uncorrelated vacuum field \( Y^\nu(t) \) [20]. The generalized input-output relation then reads

\[
Y^\text{out}(t) = \sqrt{\eta} \left[ \sqrt{2\kappa} \delta Y(t) - Y^\text{in}(t) \right] - \sqrt{1-\eta} Y^\nu(t), \tag{40}
\]

so that the estimated phase quadrature \( \delta Y^\text{est}(s) \) is given by

\[
\delta Y^\text{est}(t) = \frac{Y^\text{out}(t)}{\sqrt{2\eta \kappa}} = \delta Y(t) - Y^\text{in}(t) + \sqrt{\eta^{-1} - \eta} Y^\nu(t) / \sqrt{2\kappa}. \tag{41}
\]

After solving the QLE of Eqs. (35) by Fourier transform, one finds that the two oscillator variances in the cold-damping case are given again by Eqs. (13), but with a different position spectrum \( S_q^\text{cd}(\omega) \), that can be expressed as

\[
S_q^\text{cd}(\omega) = |\chi_{eff}^\text{cd}(\omega)|^2 [S_{th}(\omega) + S_{rp}(\omega, 0) + S_{fb}(\omega)]. \tag{42}
\]

\( S_{th}(\omega) \) is given by Eq. (15), \( S_{rp}(\omega, 0) \) is obtained by choosing \( \Delta = 0 \) in Eq. (16), and one has the additional contribution

\[
S_{fb}(\omega) = \frac{|g(\omega)|^2}{4\kappa \eta} \tag{43}
\]

due to the measurement noise that is fed back into the oscillator dynamics by the cold-damping feedback loop \((g(\omega) \text{ is the Fourier transform of } g(t)) \).

\[
\chi_{eff}^\text{cd}(\omega) = \omega_m \left[ \omega_m^2 - \omega^2 - i\omega \gamma_m + \frac{g(\omega) G \omega_m}{\kappa - i\omega} \right]^{-1} \tag{44}
\]

is the effective susceptibility of the oscillator in the cold-damping scheme, which depends upon the explicit form of the feedback transfer function \( g(\omega) \). The simplest choice, corresponding to a standard derivative high-pass filter, is

\[
g(\omega) = \frac{-i\omega g_{cd}}{1 - i\omega / \omega_{fb}}, \tag{45}
\]

which means choosing

\[
g(t) = g_{cd} \frac{d}{dt} \left[ \theta(t) \omega_{fb} e^{-\omega_{fb}t} \right]
\]

so that \( \omega_{fb}^{-1} \) plays the role of the time delay of the feedback loop, and \( g_{cd} > 0 \) is the feedback gain. The ideal derivative limit is obtained for \( \omega_{fb} \rightarrow \infty \), implying \( g(\omega) = -i\omega g_{cd} \) and therefore \( g(t) = g_{cd} \delta'(t) \). The cold-damping susceptibility of Eq. (44) can be read again as the susceptibility of an oscillator with effective resonance frequency and damping rate given by

\[
\omega_m^{eff, cd}(\omega) = \left[ \omega_m^2 + g_{cd} G \omega_m \omega_f \omega^2 (\kappa + \omega_{fb}) \right]^{1/2}, \tag{46}
\]\n
\[
\gamma_m^{eff, cd}(\omega) = \gamma_m + \frac{g_{cd} G \omega_m \omega_f (\omega_{fb} - \omega^2)}{(\kappa^2 + \omega^2)(\omega_{fb}^2 + \omega^2)}. \tag{47}
\]

The frequency dependence of the effective resonance frequency and damping depends upon the specific form of
half-plane we get one nontrivial stability condition

\[ s_{cd} = \left[ \gamma_m \kappa \omega_{fb} + g_{cd} G \omega_m \omega_{fb} + \omega_m^2 (\kappa + \omega_{fb}) \right] \times \left[ (\kappa + \gamma_m)(\kappa + \omega_{fb}) \gamma_m + \omega_m^2 - g_{cd} G \omega_m \omega_{fb} \right] - \kappa \omega_m^2 \omega_{fb} (\kappa + \gamma_m + \omega_{fb})^2 > 0. \]  

(48)

This stability condition is always satisfied in the ideal derivative feedback limit ($\omega_{fb} \to \infty$) and in the ideal adiabatic limit $\kappa \to \infty$. However, for finite values of $\omega_{fb}$ and $\kappa$, Eq. (48) implies an upper limit to the feedback gain which is given by

\[ g_2 < \epsilon_0 + \sqrt{\epsilon_0^2 + \epsilon_0^2}, \]  

(49)

where

\[ \epsilon_0 = \frac{1}{2} \left[ \frac{\omega_{fb}}{\gamma_m} \left( 1 + \frac{\gamma_m}{\kappa} + \frac{\kappa}{\gamma_m} + 1 - \frac{\omega_m^2}{\kappa \gamma_m} \right) + \frac{\omega_m^2}{\kappa \omega_{fb}} + \frac{\gamma_m + \kappa}{\omega_{fb}} - \frac{\omega_m^2}{\gamma_m \omega_{fb}} \right], \]  

(50)

\[ \epsilon_0^2 = \frac{\omega_m^2}{\kappa} + \gamma_m \kappa \left[ \frac{1}{\omega_{fb}^2 \kappa \gamma_m} \left( \frac{1}{2} \right) \right] + \omega_{fb} \left( \frac{\omega_m^2}{\kappa} + \gamma_m \kappa + \kappa \omega_m^2 \right). \]  

(51)

The system may become unstable for large gain because, for non-zero time delay, the feedback force can be out-of-phase with the oscillator motion and become an accelerating rather than a viscous force.

The exact expression for the position and momentum variances can be obtained by integrating Eq. (43) using the corresponding spectrum for the cold-damping case, given by Eq. (42). Using again the approximation of Eq. (21), one gets

\[ \langle \delta q^2 \rangle = s_{cd}^{-1} \left\{ \left( \frac{1}{2} \right) \left[ A_{cd} + \left( 1 + \frac{\omega_{fb}^2}{\kappa^2} \right) B_{cd} + C_{cd} \right] + \frac{g_{cd}^2 \omega_{fb}^2}{8 \kappa \eta} \left[ A_{cd} + B_{cd} + \frac{\omega_{fb}^2}{2 \kappa} \left[ B_{cd} + C_{cd} \right] \right] \right\}, \]  

(52)

\[ \langle \delta p^2 \rangle = s_{cd}^{-1} \left\{ \left( \frac{1}{2} \right) \left[ \left( \frac{\kappa^2 + \omega_{fb}^2}{\omega_m^2} \right) A_{cd} + \frac{\omega_{fb}^2}{\omega_m^2} B_{cd} + \omega_{fb}^2 D_{cd} \right] + \frac{\omega_{fb}^2}{\omega_m^2} B_{cd} + \omega_{fb}^2 D_{cd} \right\} \right\} + \frac{G^2}{2 \kappa} \left[ \frac{\kappa^2}{\omega_m^2} A_{cd} + \frac{\omega_{fb}^2}{\omega_m^2} B_{cd} \right]. \]  

(53)

FIG. 3: Plot of the effective mechanical frequency of Eq. (46) (a), and of the effective mechanical damping of Eq. (47) (b), versus frequency. Parameter values are $\omega_m/2\pi = 10$ MHz, $\gamma_m/2\pi = 100$ Hz, $g_{cd} = 4$, $\omega_{fb} = 3\omega_m$, $\kappa = 30\omega_m$ and $G = 0.2 \omega_m$ (dashed line), $G = 0.3 \omega_m$ (dotted line) and $G = 0.4 \omega_m$ (full line), which we shall see later correspond to an optimal feedback cooling regime.

the transfer function $g(\omega)$, and the one associated with the choice of Eq. (15) is plotted in Fig. 3 for comparison with the corresponding curves for the back-action cooling of Fig. 1. Fig. 3a shows again that in the chosen parameter regime, the frequency shift, i.e., the optical spring effect, is negligible. Cold damping is usually applied in the adiabatic limit when $\kappa, \omega_{fb} \gg \omega$ and in this limit one has $\omega_{eff,cd} \simeq \omega_m$ and $\chi_{eff,ad} \simeq \chi_{eff} \gamma_m + g_{cd} G \omega_m / \kappa = \gamma_m (1 + g_2)$, where we have defined the scaled, dimensionless feedback gain $g_2 \equiv g_{cd} G \omega_m / \kappa \gamma_m$. In this limit the only effect of cold damping is to increase the mechanical damping rate without significantly changing the resonance frequency. As a consequence, the system is stable whenever $g_{cd} \geq 0$. This is not any longer true in the general case when finite values of $\kappa$ and $\omega_{fb}$ are considered. By imposing that all the poles of $\chi_{eff}(\omega)$ lie in the lower complex
where
\[ A_{cd} = \omega_m^2 \left[ \kappa \omega_m^2 + \omega_f b \left( \omega_m^2 + \gamma_m \kappa + g_{cd} \bar{G} \omega_m \right) \right], \]
\[ B_{cd} = \omega_m^2 \kappa^2 \left( \gamma_m + \kappa + \omega_f b \right), \]
\[ C_{cd} = \omega_f b \kappa \left[ \omega_f b \left( \kappa + \gamma_m \right) + \omega_f b \left( \kappa + \gamma_m \right)^2 \right] + \gamma_m \left( \omega_m^2 + \kappa^2 + \kappa \gamma_m \right), \]
\[ D_{cd} = \omega_f^2 b \left[ \gamma_m \left( \omega_m^2 + \kappa^2 + \kappa \gamma_m \right) + (\kappa + \gamma_m) g_{cd} \bar{G} \omega_m \right] + \omega_f b \left( \omega_m^2 + \kappa \gamma_m + g_{cd} \bar{G} \omega_m \right) + \kappa \omega_m^2 \left( \omega_m^2 + \gamma_m \kappa \right). \]

Eqs. (52) and (53) show that also with cold damping \( \langle \delta q^2 \rangle \neq \langle \delta p^2 \rangle \), i.e., energy equipartition does not hold in general.

The optimal cooling conditions in the cold-damping scheme can be obtained by minimizing the sum of the variances of Eqs. (52) and (53), which is non trivial in general. Since, however, cold-damping feedback is designed to work only within the adiabatic limit, we can restrict the discussion to the bad cavity limit where \( \kappa \gg \omega_m, \gamma_m \). In fact, the feedback force is an additional viscous force that is able to overdamp the mechanical oscillator only when the output signal \( \delta Y_{est}(t) \) is proportional to the oscillator position \( \delta q(t) \), which happens when \( \kappa \) is much larger than the relevant frequencies \( \omega \) of the mechanical motion. In the good cavity limit (\( \kappa \ll \omega_m, \gamma_m \)) on the contrary, the output signal \( \delta Y_{est}(t) \) is proportional to the time integral of the oscillator position \( \delta q(t) \) and therefore the feedback force is proportional to the oscillator position rather than to its velocity. This means that in the good cavity limit the feedback loop has no cold-damping effect, because it increases the mechanical frequency, \( \omega_{m,cd}^2 \simeq \left[ \omega_m^2 + g_{cd} \bar{G} \omega_m \right]^{1/2} \), without appreciably modifying the mechanical damping (see Eqs. (44), (46), and (47).

We discuss the expressions of \( \langle \delta q^2 \rangle \) and \( \langle \delta p^2 \rangle \) in the adiabatic limit by distinguishing two situations that depend upon the value of the feedback bandwidth \( \omega_f b \): i) very large bandwidth, \( \omega_f b \gg \kappa \gg \omega_m, \gamma_m \), where the feedback is practically instantaneous; ii) finite bandwidth, \( \kappa \gg \omega_f b \gg \omega_m, \gamma_m \). In the first case one has
\[ \langle \delta q^2 \rangle \simeq \frac{\bar{n} + \frac{1}{2} + \frac{\zeta}{4} + \frac{g_{cd} \gamma_m}{\kappa}}{1 + \frac{g_{cd} \gamma_m}{\kappa}}, \]
\[ \langle \delta p^2 \rangle \simeq \frac{\bar{n} + \frac{1}{2} \left( 1 + \frac{g_{cd} \gamma_m}{\kappa} \right) + \frac{g_{cd} \gamma_m}{4 \eta \zeta \omega_m^2}}{1 + \frac{g_{cd} \gamma_m}{\kappa}} \omega_f b \gamma_m \omega_m \]
where we have defined the scaled dimensionless input power \( \zeta = 2G \omega_m^2 / \kappa \gamma_m \). These results provide the generalization of the results of Refs. 20, 21, where the quantum limits of cold-damping have been already discussed within the adiabatic limit. In fact, Eqs. (58)–(59) reproduce the results of Ref. 21 in the large-bandwidth limit of the feedback except for the addition of the non-adiabatic correction term \( g_{cd} \gamma_m / \kappa \) for both \( \langle \delta q^2 \rangle \) and \( \langle \delta p^2 \rangle \). The almost instantaneous feedback regime \( \omega_f b \gg \kappa \gg \omega_m, \gamma_m \) is not convenient for cooling because of the last contribution to \( \langle \delta p^2 \rangle \), which is very large since it diverges linearly with \( \omega_f b \). This is due to the fact that the derivative feedback injects a large amount of shot noise when its bandwidth is very large.

In the other limit where the feedback delay time is comparable to the oscillator timescales, that is, \( \kappa \gg \omega_f b \sim \omega_m \gg \gamma_m \), one has
\[ \langle \delta q^2 \rangle \simeq \frac{\bar{n} + \frac{1}{2} + \frac{\zeta}{4} + \frac{g_{cd} \gamma_m}{\kappa}}{1 + \frac{g_{cd} \gamma_m}{\kappa}} \frac{\omega_f b \gamma_m \omega_m}{\bar{n} + \frac{1}{2} + \frac{\zeta}{4} + \frac{g_{cd} \gamma_m}{\kappa}} \omega_f b \gamma_m \omega_m \]
\[ \langle \delta p^2 \rangle \simeq \frac{1 + \frac{g_{cd} \gamma_m}{\kappa} \left( \frac{g_{cd} \gamma_m}{4 \eta \zeta \omega_m^2} \right) \left( 1 + \frac{g_{cd} \gamma_m}{\kappa} \right)}{1 + \frac{g_{cd} \gamma_m}{\kappa}} \omega_f b \gamma_m \omega_m \]
\[ \left( \frac{\bar{n} + \frac{1}{2} + \frac{\zeta}{4} + \frac{g_{cd} \gamma_m}{\kappa}}{1 + \frac{g_{cd} \gamma_m}{\kappa}} \right) \right]. \]

These results generalize those of Refs. 20, 21, which were restricted to the adiabatic limit \( \kappa \sim \infty \), and partially modify their conclusion that one can always achieve ground-state cooling in the large feedback-gain limit \( g_2 \simeq \zeta \sim \infty \) (\( \eta = 1 \)). This is not true in general.

From Eq. (60) it is clear that, when \( g_2 \simeq \zeta \gg 1, \omega_f b / \omega_m^2 \), one obtains \( \langle \delta q^2 \rangle \simeq 1/2 + \omega_m^2 / 4 \omega_f b^2 (\bar{n} + \frac{1}{2}) (1 + \omega_m^2 / \omega_f b^2) \), which implies that the ground state is approached when \( \omega_m / \omega_f b \ll 1 \) and \( \bar{n} / g_2 \ll 1 \). However, in the same limit, Eq. (61) yields \( \langle \delta p^2 \rangle \simeq 1/2 + \omega_m^2 / 4 \omega_f b^2 (g_2 \gamma_m / \omega_f b) + \bar{n} / g_2 (1 + \omega_m^2 / \omega_f b^2 + g_2 \gamma_m / \omega_f b) \), showing that the feedback bandwidth \( \omega_f b \) cannot be too large, because otherwise \( \langle \delta p^2 \rangle \) becomes too large.

The best cooling regime is instead achieved for \( \omega_f b \sim 3 \omega_m \) and \( g_2 \simeq \zeta \) (i.e. \( g_{cd} \simeq 2G / \omega_m \)), i.e. for large but finite feedback gain. This is consistent with the fact that stability imposes an upper bound to the feedback gain when \( \kappa \) and \( \omega_f b \) are finite. The optimal cooling regime for cold damping is illustrated in Fig. 2 where \( n_{eff} \) is plotted versus the feedback gain \( g_{cd} \) and the input power \( P \), at fixed \( \kappa = 3 \omega_m \) (bad-cavity condition) and \( \omega_f b = 3.5 \omega_m \). We find a minimum value \( n_{eff} \simeq 0.2 \), corresponding to an effective temperature \( T \simeq 0.27 \) mK for \( g_2 \simeq \zeta \simeq 10^4 \).

Lower values of \( n_{eff} \) can be obtained only if the quality factor \( \omega_m / \gamma_m \) is further increased.

**CONCLUSIONS**

We have developed a general quantum Langevin treatment of radiation-pressure ground-state cooling of a micromechanical oscillator, extending previous treatments 17, 18, 20, 21, 28, 29 to the full parameter range of a stable cavity. Both cavity self cooling and cold damping are able to approach the ground state, and the comparison of the optimal cooling conditions for both
FIG. 4: (Color online) a) Effective mean vibrational number \( n_{\text{eff}} \) versus the feedback gain \( g_{\text{dc}} \) and the scaled input power \( P/P_0 \) (\( P_0 = 100 \text{ mW} \)), around the optimal cooling regime for \( \omega_m/2\pi = 10 \text{ MHz}, \gamma_m/2\pi = 100 \text{ Hz} \), \( m = 250 \text{ ng} \), a cavity of length \( L = 0.5 \text{ mm} \) driven by a laser with wavelength 1064 nm. The feedback bandwidth is \( \omega_{fb} = 3.5\omega_m \). The feedback gain is \( \kappa = \omega_m \). The oscillator reservoir temperature is \( T = 0.6 \text{ K} \), corresponding to \( n \approx 1250 \). The minimum value \( n_{\text{eff}} \leq 0.2 \) corresponds to an effective temperature \( T_{\text{eff}} \approx 0.27 \text{ mK} \).

(b) Effective mean vibrational number \( n_{\text{eff}} \) versus \( \kappa/\omega_m \) and \( \omega_{fb}/\omega_m \) at fixed input power \( P_0 = 100 \text{ mW} \) and feedback gain \( g_{\text{dc}} = 0.8 \). The other parameters are as in (a).

schemes shows that self cooling is preferable for a good cavity (\( \kappa < \omega_m \)), while cold damping is more convenient for a bad cavity (\( \kappa > \omega_m \)).

[33] Dividing by \( \sqrt{\eta} \) in the definition of \( \delta Y^{\text{est}} \) is customary in quantum feedback theory [H. M. Wiseman and G. J. Milburn, Phys. Rev. Lett. 70, 548 (1993)], and means assuming that the feedback action automatically compensates for the loss of signal due to non-ideal detection, independently of the value of the feedback gain \( g_{\text{cd}} \). However this choice may be misleading because the parameter \( g_{\text{cd}} \) becomes the feedback gain without taking into account this automatic compensation and it is therefore dependent upon \( \eta \). A simpler choice which avoids this problem is to define \( \delta Y^{\text{est}} \) without dividing by \( \sqrt{\eta} \), i.e.,

\[
\delta Y^{\text{est}}(t) \equiv \frac{Y^{\text{out}}(t)}{\sqrt{2\kappa}},
\]

which is a sort of output phase quadrature integrated over the cavity bandwidth. In this way the parameter \( g_{\text{cd}} \) coincides with the actual gain of the feedback loop. All the subsequent equations of the paper remain correct provided that one performs the rescaling \( g(\omega) \rightarrow \sqrt{\eta}g(\omega) \), which implies \( g_{\text{cd}} \rightarrow \sqrt{\eta}g_{\text{cd}} \) and \( g_2 \rightarrow \sqrt{\eta}g_2 \). This means in particular that the measurement noise term of Eq. (44) is independent of \( \eta \), while the feedback correction to the mechanical susceptibility in Eq. (45) becomes proportional to \( \sqrt{\eta} \). In the limit \( \eta \rightarrow 0 \) therefore feedback is no longer able to modify the mechanical response and has the only effect of adding the measurement noise.
