The Comparison Between Non-High Risk Patients with and Without Cancer Diagnosed with Pulmonary Embolism

Kanseri Olan ve Olmayan Yüksek Riskli Olmayan Pulmoner Emboli Hastalarının Karşılaştırılması

ABSTRACT

Objective: This study aimed to compare the pulmonary embolism (PE) location and clot burden on computed tomography pulmonary angiography (CTPA), the degree of right ventricular dysfunction (RVD), D-dimer, and cardiac troponin I (cTnI) levels, and the presence of a lower extremity deep venous thrombosis (DVT) in patients with and without cancer diagnosed with a non high risk pulmonary embolism (PE).

Method: We calculated Miller score for each patient for clot burden. The location of PE was also evaluated at CTPA. D-dimer and cardiac cTnI levels were measured. Patients had echocardiography for RVD and lower extremity color flow Doppler ultrasonography for DVT.

Results: The study included 71 patients with PE. The patients were divided into two groups according to the presence of cancer. There was no statistically significant difference for D-dimer levels (P=0.15), PE location (p=0.67), clot burden (P=0.34), RVD (P=0.28) and DVT (P=0.33) between groups (P=0.15). Cancer patients diagnosed as PE had statistically significantly higher levels of cTnI than those who were diagnosed as PE without cancer (P=0.03).

Conclusion: There was no significant difference between patients diagnosed as PE with and without cancer in terms of D-dimer levels, clot burden and emboli location, RVD and DVT. cTnI levels were higher in non-high risk PE patients with cancer than these patients without cancer.

Keywords: Pulmonary embolism, cancer, thrombus, troponin, D-dimer

ÖZ

Amaç: Bu çalışma, kanserli olan ve olmayan yüksek riskli olmayan pulmoner emboli (PE) hastalarında pulmoner bilgisayarlı tomografik anjiyografide (CTPA), sağ ventrikül disfonksiyonu (SVD), serum D-dimer, serum kardiyak troponin I (kTnI) ve alt ekstremitelerin ven trombozu (DVT) varlığının karşılaştırılması amaçlanmıştır.

Yöntem: Her hasta için trombus yükü Miller Skoru ile hesaplandı. PE yerine PTBA’dan değerlendirildi. Serum D-dimer, kTnI düzeyleri ölçülüyor. Hastalara SVD için ekokardiyografi ve DVT için alt ekstremitelerin renkli doppler ultrasonografi yapıldı.

Bulgular: PE tanıtılmış bir hasta çalışmaya alınmıştı. Hastalar kanser varlığına göre iki gruba ayrıldı. İkinci grubun D-dimer düzeyleri (p=0.15), PE yerin (p=0.67), trombus yükü (p=0.34), SVD (p=0.28) ve DVT (p=0.33) yönünden istatistiksel anlamlı bir fark saptanmadı. Kanser olmayan PE tanısi konulan hastalar, kanser tanısı olmayanlara göre istatistiksel olarak anlamlı derecede daha yüksek kTnI düzeylerine sahipti (p=0.03).

Sonuç: Kanserli olan ve olmayan PE tanısi konulan hastalar arasında D-dimer, trombus yükü, emboli yerleştirmi, SVD ve DVT varlığı açısından fark saptanmadı. Kanserli olan yüksek riskli olmayan PE hastalarında kTnI düzeyleri, kanserli olmayan yüksek riskli olmayan PE hastalarından daha yüksekti.

Anahtar kelimeler: Pulmoner emboli, kanser, trombus, troponin, D-dimer

INTRODUCTION

Cancer is a well-recognized risk factor for venous thromboembolic disease and the risk of pulmonary embolism (PE) and the overall risks of venous thromboembolism (VTE) in cancer patients is four times higher than the risk in the general population\(^1\,2\). In addition to its prevalence, PE increases morbidity and mortality in cancer patients\(^2\). In comparison with the general population, in cancer patients with a diagnosis of PE the incidence of major adverse events is 3-fold higher including major bleeding on anticoagulation, cardiovascular collapse and shock, recurrence of PE within 30 days\(^3\,5\). Accordingly, an alternative management strategy may be indicated for these patients.

The prognosis of patients with a PE is related with their ability to compensate for and to overcome the impairment in gas exchange, right ventricular strain, and reduced left ventricular filling pressures resulting from embolism. While baseline hemodynamic status and underlying disease are important prognostic indicators\(^6\), additional objective findings may be used for identifying patients at high risk for a poor outcome. Localization of emboli and the extent of clot burden (the obstructive index) can be assessed with computed tomography pulmonary angiography (CTPA) and it may be used for stratification of patients with PE\(^7\). The amount of thrombus burden determines the extent of hemodynamic collapse and damage to gas exchange\(^6\). However, in one study no correlation was observed between obstruction index and prognosis\(^7\). Echocardiography findings, troponin elevation, and brain natriuretic peptide (BNP) levels are also routinely used to define risk stratification of patients with PE\(^1\). PE in patients with shock or persistent arterial hypotension was defined as high-risk PE and others were defined as non-high-risk PE in the absence of these.

This study aimed to compare the PE location and clot burden on CTPA, the degree of right ventricular dysfunction (RVD), D-dimer, and cardiac troponin I (cTnI) levels, and the presence of a lower extremity deep venous thrombosis (DVT) in patients with or without cancer diagnosed with a non high-risk PE.

MATERIAL and METHODS

Study design:
This study was conducted in the Pulmonology Department of Sultan 2. Abdulhamit Han Training and Research Hospital. Imaging and clinical data were retrospectively reviewed. The study was approved by the Ethics Review Board. Patients included in the study were older than 18 years of age and underwent at least one CTPA to confirm the diagnosis of PE. In order to confirm the diagnosis of PE, CTPA was evaluated and reported by an experienced radiologist interested in chest radiology. A Miller Score was calculated for each patient, according to the degree of contrast filling defect found on CTPA\(^8\). The localization of the embolism was also evaluated at CTPA and recorded as right, and left-sided or bilateral PE. Cancer was diagnosed pathologically and all types of cancer patients were included in the study. Patients with cancer in remission were excluded.

D-dimer and cTnI measurements were performed in the emergency department. Acute coronary syndrome and other cardiac diseases were ruled out by electrocardiography and echocardiography performed by a cardiology consultant. After hospitalization, lower extremity color Doppler ultrasonography was performed. Cases with PE were classified as low-risk, intermediate risk and high-risk patients based on early mortality risk according to the guidelines\(^1\). High-risk patients were hemodynamically unstable ones with shock or hypotension. Low-risk patients had no signs of RVD and elevated cardiac biomarkers. Intermediate-risk patients had either one (or none) positive or both positive but pulmonary embolism severity index (PESI) class III-IV or simple PESI \(\geq 1\) score. Patients with high-risk PE, who were treated in intensive care unit and
received thrombolytic therapy, were not included in the study. The patients with and without cancer diagnosed in terms of a non-high risk PE were compared in terms of the PE location and clot burden on CTPA, D-dimer and, cTnI levels, the presence of right RVD, and DVT.

**Statistical Analysis:**
In the analysis, PSPP (free software under the terms of the GNU General Public License) was used. Descriptive analyzes (frequency distributions, percentages, mean, median, and standard deviation) and Kolmogorov-Smirnov normality distributions were used for the analysis of data. Mann-Whitney U test was used to measure the difference between groups since the data was not normally distributed. Chi-square test was used for the differences between discrete variables. The results were evaluated at 95% confidence interval and with p<0.05 significance level.

**RESULTS**

The study included 71 patients. All patients were diagnosed as having a PE by CTPA. There were 20 patients in the malignancy group and 51 patients constituted the group without malignancy. The mean age of the group without malignancy (male 49%, and female 51%) was 62.86±20.80 years. The mean age of the group with malignancy (male 55%, and female 45%) was 70.90±15.92 years (Table 1). There was no statistically significant difference for age and gender between groups (p values are=0.18 and 0.65, respectively).

The mean D-dimer levels of patients with and without cancer were 2134.82±1527.96 ng/mL, and 1504.95±1265.98 ng/mL, respectively. (Table 2). There was no statistically significant difference for D-dimer levels between the two groups (P=0.15).

Of the patients without cancer, 41.2% had emboli on the right, 17.6% on the left and 41.2% on both sides. In patients with cancer, emboli were on the right side in 40.0%, on the left side in 10.0% and on both sides in 50.0%. There was no statistically significant difference as for the localization of emboli between the two groups (P=0.67). The mean Miller scores were 6.55±3.33, and 5.94±3.58 in patients with, and without cancer, respectively. There was no statistically sig-

| Emboli Localization (n, %) | No Cancer (n=51) | Cancer (n=20) | Total (n=71) | P-value |

| cTnI (ng/L)               | 4±7             | 23±54        | 10±30        | 0.03    |

| n: number, SD: standard deviation, DVT: deep venous thrombosis, RVD: right ventricular dysfunction, cTnI: cardiac troponin I. |
significant difference for clot burden between the two groups (P=0.34). RVD was found in 45%, and 31.4% of patients with, and without cancer, respectively. There was no statistically significant difference as for the presence of RVD between groups (P=0.28). The mean cTnl levels of patients with and without cancer were 23±54 ng/L, and 4±7 ng/L, respectively. Patients with a PE in the setting of malignancy had significantly higher levels of cTnl than those without diagnosis of cancer (P=0.03). DVT was detected in 50%, and 37.3% of the patients with, and without cancer. There was no statistically significant intergroup difference as for the presence of DVT (P=0.33).

DISCUSSION

There was no difference between patients diagnosed as PE with and without cancer in terms of D-dimer levels, clot burden and emboli location, RVD and DVT, but the cTnl level was significantly higher in the patients with PE in the setting of an underlying diagnosis of cancer in this study.

Troponin elevation at the time of diagnosis of acute PE is an important prognostic laboratory parameter. Patients with PE and elevated troponin level are at high risk of short-term mortality and other adverse outcomes. Increased serum cTnl levels may suggest the diagnosis of severe PE in clinic and echocardiographic suspicion of PE. Increased troponin levels were found as an independent prognostic marker among PE patients with increased brain natriuretic peptide (BNP) levels. In another study, although higher cTnl levels predicted fatal PE, cTnl was not an independent predictor of 30-day all-cause mortality in hemodynamically stable patients with PE. In addition to mortality risk stratification, cTnl levels were also found as predictive of RVD in patients presenting with PE, though the ability of cTnl to predict RVD was higher in patients without cancer than in those with cancer history. In our study, the cTnl level was significantly higher in patients with PE in the setting of underlying diagnosis of cancer.

PE is an important clinical problem and patients with PE have a high mortality rate. Cancer frequently causes thrombosis because of its prothrombotic effect. Patients with cancer have a four to six times higher risk for VTE compared to those without. Khorana et al. showed that the mortality risk of VTE patients with cancer was higher than patients without. Hospitalization due to VTE, use of prolonged anticoagulants, treatment-related complications, VTE recurrence and delay in cancer treatment increased morbidity in cancer patients.

Recurrence of thromboembolism and treatment-related complications are more common in patients with venous thrombosis diagnosed with cancer than in patients without. Because of these issues, different approaches to the treatment of PE are recommended in cancer patients. Measurement of D-dimer levels is usually used to exclude PE. Although measurement of D-dimer using ELISA (Enzyme-linked immunosorbent assay) method is apparently reliable to rule out PE in cancer patients but using a high cut-off value of D-dimer in cancer patients may increase its clinical usefulness. Patients with cancer have higher levels of D-dimer in general, and Ay et al. found that there was an association between high D-dimer levels and poor survival and increased mortality risk in cancer patients. In our study, D-dimer levels did not differ between patients with and without cancer who were diagnosed with a PE.

In this study, we showed that, there was no difference for clot burden between patients diagnosed as PE with and without cancer. Consensus has not been reached as to whether the embolic burden as assessed on a CTPA has a role in the risk stratification of patients diagnosed with PE. Clot burden may be included in the risk stratifying tools such as PESI for patients with PE. While larger clot volume induces RVD more often, it has not been associated with short-term mortality.
Moreover, no correlation was found between the obstruction index on CTPA and prognosis\(^7\). At the time of writing clot burden as assessed by CTPA was not included in the risk classification algorithms\(^1\).

In our study, there was no difference in RVD between patients with a PE regardless of their cancer status. Evaluating patients with acute PE for the presence of RVD using Doppler imaging echocardiography and/or laboratory markers may provide clinical utility as a strategy for risk stratification\(^21\). There is no definitive decision on the role of RVD in predicting prognosis in hemodynamically stable patients with PE\(^22,23\), and there is mounting evidence of its usefulness for risk stratification. RVD detected on admission is associated with increased risk of mortality in low-risk patients with PE\(^22,23\). While echocardiographic examination is not recommended as of the diagnostic work up in hemodynamically stable patients with a suspected, but not proven PE; echocardiography plays a role in the prognostic stratification of patients diagnosed with an intermediate or low-risk PE\(^24\).

Cancer patients have an increased risk of developing all forms for VTE, both DVTs and PEs, compared with patients without cancer\(^25\). DVT can be detected with advanced diagnostic methods in about 70% of the patients with PE\(^11\). With that in mind, when dealing with PE possibility, it is suggested that compression ultrasound is safe and proven particularly efficient as a frontline test, especially in elderly patients; however, Girard et al.\(^26\) did not support routine screening for DVT in patients who already have a CTPA-proven PE. The overall incidences of PE and DVT in patients hospitalized with cancer were twice the rates of non-cancer patients\(^27\). In our study, we found that a DVT was coexistent with a PE more frequently in patients with cancer than those without, but the difference was not statistically significant.

**Limitations:**

There are some limitations in this study. The study was performed retrospectively using the electronic data system of our hospital. Patients with high-risk PE who were treated in intensive care or received thrombolytic therapy were excluded. Another limitation of the study was the small number of patients included in our study. Cancer patients were not classified according to the histopathological cell types.

**CONCLUSION**

There was no difference between patients with and without cancer diagnosed with a non-high-risk PE in terms of D-dimer, RVD, DVT, clot burden and localization of emboli. The cTnI levels were higher in non-high-risk PE patients with cancer than those without cancer. Given the prognostic implications of an elevated cTnI levels in the setting of PE, patients with cancer and a PE may have a more severe prognosis. Comparison of patients with and without cancer with PE will be important in determining the clinical approach to these patients in the future.
