Abstract

Hydrogen sulphide (H₂S) is emerging as a potential messenger molecule involved in modulation of physiological processes in animals and plants. In this report, the role of H₂S in modulating photosynthesis of Spinacia oleracea seedlings was investigated. The main results are as follows. (i) NaHS, a donor of H₂S, was found to increase the levels, internal concentration of H₂S, and the activity and the function of thiol redox modification may underlie the amelioration of photosynthesis and that H₂S

Abbreviations: AQE, quantum yields; CE, carboxylation efficiency; CCO, cytochrome oxidase; Ci, intercellular CO₂ concentration; Fmax, maximal fluorescence yield; Fo, minimal fluorescence yield; FRX, ferredoxin; FTR, ferredoxin thioredoxin reductase; GADPH, glyceraldehyde-3-phosphate dehydrogenase; GYX, glycolate oxidase; gₚ, stomatal conductance; H₂S, hydrogen sulphide; LCD, L-cysteine desulphydrase; Lcp, light compensation point; Lsp, light saturation point; NADP-MDH, NADP-malate dehydratase; OAS, O-acetylserine(thiol)lyase gene; OAS-TL, O-acetylserine(thiol)lyase; PAR, photosynthetically active radiation; Pmax, maximum net photosynthetic rate; Pn, net photosynthetic rate; PSI, photosystem II; qRT-PCR, quantitative real-time RT-PCR; Rd, dark respiration rate; RuBISCO, ribulose-1,5-bisphosphate carboxylase; RBCL, RuBISCO large subunit; RBCS, RuBISCO small subunit; SERAT, serine acetyltransferase; TRX-f, thioredoxin f; TRX-m, thioredoxin m.

**Introduction**

Hydrogen sulphide (H2S) is a colourless gas with a strong odour of rotten eggs. The toxicity of H2S at high concentration has been substantiated for almost 300 years (Lloyd, 2006). More recently, many studies have revealed that H2S can act as a signalling molecule similar to nitric oxide (NO) and carbon monoxide (CO) in animals at lower concentrations, and participate in various biological processes, such as smooth muscle relaxation, hippocampal long-term potentiation, brain development, blood pressure, and inflammation (Hosoki et al., 1997; Wang, 2002; Li et al., 2006; Yang et al., 2008; Zhao et al., 2001). However, there have been few studies on the involvement of H2S in modulation of physiological processes in plant.

H2S is thought to be released from cysteine via a reversible O-acetylserine(thiol)lyase (OAS-TL) reaction in plants (Sekiya et al., 1982; Wirtz et al., 2004). It was reported that higher plants could emit H2S when exposed to excess sulphur and cysteine (Sekiya et al., 1982; Rennenberg, 1983). Moreover, the emission of H2S in plants is dependent on light (Wilson et al., 1978). In addition, short-term exposure of *Brassica oleracea* to a high level of H2S resulted in a decrease in the activity of adenosine 5'-phosphosulphate reductase in the shoot, and an increase in the thiol content and cysteine content in the shoot and root (Westerman et al., 2000). Very recently it was reported that H2S promotes wheat seed germination, alleviates oxidative damage against copper stress (Zhang et al., 2008a), counteracts chlorophyll loss, and alleviates oxidative damage due to osmotic stress in sweet potato seedling leaves (Zhang et al., 2009). Furthermore, boron toxicity and aluminium toxicity were alleviated by H2S (Wang et al., 2010; Zhang et al., 2010). Additionally, a low H2S concentration can promote the embryonic root length of *Pisum sativum* (Li et al., 2010). All these investigations indicate that the study of H2S in plants is just beginning.

It is well known that the increase in photosynthesis can be achieved by enhancing the activity of ribulose-1,5-bisphosphate carboxylase (RuBISCO) (Krantev et al., 2008). RuBISCO plays a cardinal role in controlling photosynthesis and is composed of eight large subunits encoded by a single gene (*RBCL*) in the chloroplast genome and eight small subunits encoded by a nuclear multigene family (*RBCS*) (Dean et al., 1989). Changes in RuBISCO synthesis have been primarily explained by changes in transcript abundance of *RBCL* and *RBCS* in response to various external and/or internal signals (Nishimura et al., 2008; Suzuki et al., 2010). In addition, the oxidation of glycolate to glyoxylate in higher plants is catalysed by glycolate oxidase, which is located in the peroxisomes and performs an essential role in the oxidative photorespiration cycle accompanying photosynthetic CO2 assimilation (Zelitch and Ochoa, 1953; Zelitch et al., 2009). Meanwhile, photorespiration also involves a cooperative interaction among enzymes localized in chloroplasts, mitochondria, and peroxisomes, and is performed by the glycolate pathway. Glycolate oxidase is the first enzyme in this pathway (Yamaguchi and Nishimura, 2000).

A previous study has shown that NO could increase the photosynthetic rate of *Spinacia oleracea* and lead to more biomass accumulation (Jin et al., 2009). Photosynthesis was altered by NO through changing the ultrastructure of chloroplasts in flax leaf blades (Batasheva et al., 2010). Likewise, CO is able to prevent the iron deficiency-induced chlorosis and improve the chlorophyll accumulation in *Arabidopsis thaliana* (Kong et al., 2010). As for the effect of H2S on photosynthesis, it was reported that excess sulphide (1 mM) resulted in inhibition of photosystem II (PSII) in cyanobacteria and tobacco chloroplasts (Oren et al., 1979), and that a high sulphide concentration (2 mM) depressed the growth and photosynthesis in a mangrove plant (Lin and Sternberg, 1992). However, it is not clear whether a low concentration of H2S is involved in regulation of photosynthesis in plants.

In this study, NaHS, a donor of H2S frequently used in animal research, was adopted to understand further the roles of H2S in physiological processes of photosynthesis and grana lamella formation in *S. oleracea*. The results indicated that the net photosynthesis (Pn), RuBISCO, OAS-TL, and L-cysteine desulphydrase (LCD) activities and other photosynthetic characteristics were altered by exogenous application of a low concentration of NaHS. The number of grana lamellae stacking into functional chloroplasts was also increased markedly. Furthermore, it was demonstrated that seedlings treated with 100 μM NaHS increased the expression of the genes *RBCL* and *RBCS*, and those of the ferredoxin/thioredoxin system, and the protein expression level of the RuBISCO large subunit (RuBISCO LSU), but significantly decreased the gene expression of glycolate oxidase (GYX) and cytochrome oxidase (CCO). It is concluded that H2S acts as a signalling molecule that participates in enhancing photosynthesis and chloroplast development during *S. oleracea* growth.

---

**Materials and methods**

*Plant growth and treatments*

Seeds of *S. oleracea* were first sterilized in 75% ethanol for 3 min and then in 10% sodium hypochlorite solution for an additional
H$_2$S enhances photosynthesis of Spinacia oleracea

10 min followed by washing with distilled water and germinating in a soil/vermiculite (1:1) mixture. Two-week-old seedlings were transferred to 1/2 strength Hoagland’s solution (pH 6.0) in a controlled growth chamber with a light/dark regime of 15/9 h, relative humidity of 80%, temperature of 21/27 °C, and a photosynthetically active radiation (PAR) of 190 μmol m$^{-2}$ s$^{-1}$. NaHS was purchased from Sigma and used as the exogenous H$_2$S donor as described by Hosoki et al. (1997). Seedlings were divided into two groups for further treatment. In the first group, seedlings were supplied with various concentrations of NaHS (0, 10, 100, 500, and 1000 μM) for 30 d. The solutions were changed every 3 d. In the second group, seedlings were treated with the optimal concentration of NaHS (identified from the trial experiment of the first group) for 0, 6, 12, 24, and 36 h. In order to distinguish the possible roles of H$_2$S, HS$^-$, Na$^+$, or other sulphur-containing components in photosynthesis, a series of chemicals such as Na$_2$S, Na$_2$SO$_4$, Na$_2$SO$_3$, NaHSO$_4$, NaHSO$_3$, and NaAC were used as the controls of NaHS. The leaves of *S. oleracea* were collected and immediately frozen in liquid N$_2$ and stored at −80 °C for further analyses, with the exception that fresh leaves were used for gas exchange, transmission electron microscopy, and chlorophyll fluorescence experiments.

**Determination of chlorophyll and soluble protein contents**

Chlorophyll content was measured according to Lichtenthaler (1987) with some modifications. After extraction using 10 ml of 80% (v/v) aqueous acetone, the content of total chlorophyll and the chlorophyll *a/b* ratio (chl *a/b*) were calculated from the absorbance of leaf chlorophyll extracts at 470, 646, and 663 nm. Soluble protein content was measured according to Bradford (1976) using the Bio-Rad protein assay reagent (Bio-Rad, Hercules, CA, USA) with bovine serum albumin (BSA) as the standard protein.

**Determination of the content of non-protein thiols**

The total content of non-protein thiols (NPTs) in plants was measured according to Del Longo et al. (1993) with minor modifications. A plant sample (0.2 g) was homogenized in 1 ml of 5% (w/v) sulphosalicylic acid and incubated on ice for 30 min. The homogenate was centrifuged at 8000 g for 15 min at 4 °C and the NPTs content in the supernatant was measured. The reaction mixture containing 200 μl of the supernatant, 2.0 ml of 0.2 M TRIS-HCl (pH 8.2), and 0.15 ml of 10 mM 5,5'-dithiobis-(2-nitrobenzoic acid) (DTNB) was incubated at room temperature for 20 min. After incubation, the absorbance was measured at 412 nm. An aliquot without DTNB was used to adjust the spectrophotometer to zero absorbance, and glutathione (GSH) was used as a standard.

**Determination of glutathione and cysteine levels**

Both GSH and cysteine levels in leaf tissues were determined after labelling with monobromobimane (mBBr) and separation by reverse-phase HPLC using the following procedure (Kosower et al., 1987). Fresh leaves (0.1 g) were added to 1 ml of 0.1 M HCl with 0.1 g of polyvinylpolypyrrolidone (PVPP; pre-washed with 0.1 M HCl). The samples were shaken for 60 min at room temperature. After centrifugation (15 min at 20 000 g, 4 °C), 100 μl of the supernatant were added to 100 μl of 200 mM 2-(cyclohexylamino)ethanesulfonic acid (CHES), pH 8.5. Reduction of the total disulfides was performed by adding 70 μl of 100 mM dithiothreitol (DTT). After 1 h incubation at room temperature, free thiols were labelled with mBBr. Then 10 μl of 16 mM mBBr in acetonitrile were added to the mixture for 15 min in the dark at room temperature. The reaction was stopped by adding 220 μl of 10 mM methysulfonylacid. The samples were centrifuged at 20 000 g for 40 min at 4 °C and then filtered through a 0.2 μm nylon filter, and separation of thiols was carried out on an Agilent Hypersil BDS-C18 column using an HP1100 HPLC system. Mixed standards treated exactly as the sample supernatants were used as a reference for the quantification of cysteine and GSH content.

**Transmission electron microscopy**

Leaves were cut into 0.5 × 0.5 mm pieces and immediately fixed with 2.5% glutaraldehyde (in 0.1 M sodium phosphate buffer, pH 7.0) at room temperature for 4 h. After three 20 min rinses, the samples were post-fixed with 1% OsO$_4$ in the same buffer for 4 h at room temperature, followed by three buffer rinses. Samples were dehydrated in an acetone series, embedded in Spurr’s resin, and sectioned with a Leica EM UC6 ultramicrotome (Leica Microsystems GmbH, Wetzlar, Germany). The ultrathin sections (70–90 nm) were stained with uranyl acetate and lead citrate. A Philips CM 100 transmission electron microscope (Philips, Eindhoven, The Netherlands) at 80 kV was used for ultrastructure imaging of chloroplasts. At least three seedlings and >30 individual chloroplasts were observed for each indicated time point by following the methods of Chang et al. (2008).
where \( \theta \) is the convexity.

The \( P_{n} \) was modelled as a function of intercellular \( \text{CO}_2 \) concentration (Ci). This application fits a model curve described by the rectangular hyperbola (Olsson and Leverenz, 1994):

\[
P_{n} = \frac{CE \times Ci \times P_{\text{max}}}{CE \times Ci + P_{\text{max}}} - Re
\]

where \( P_{n} \) is the assimilation rate, \( CE \) is the carboxylation efficiency, \( Ci \) is the intercellular \( \text{CO}_2 \) concentration, \( P_{\text{max}} \) is the assimilation at saturating \( \text{CO}_2 \), and \( Re \) is the respiratory processes (dark and light). Experimental data are fitted by first obtaining initial estimates of \( CE \) and \( Re \) values using linear regression over the lower part of the curve and estimating \( P_{\text{max}} \) from the largest value. Subsequently a least-squares fit was obtained and values for \( CE \), \( Re \), and \( P_{\text{max}} \) were presented.

Chlorophyll fluorescence was measured using a fluorescence monitoring system PAM-2100 (Heinz Walz, Effeltrich, Germany). Leaves were kept in darkness for adaptation for >30 min prior to the measurement. Two measurements were taken from each seedling to determine \( F_{0} \), the initial fluorescence as all reaction centres are open, and \( F_{\text{m}} \), the maximum fluorescence as all reaction centres are closed. Finally, the maximal photochemical efficiency of PSII (\( F_{v}/F_{\text{m}} \)) was calculated according to Krause and Weis (1991) using the following equation:

\[
F_{v}/F_{\text{m}} = \frac{F_{v} - F_{0}}{F_{\text{m}}}
\]

Measurement of endogenous \( \text{H}_2\text{S} \)

Endogenous \( \text{H}_2\text{S} \) was determined by the formation of methylene blue from dimethyl-p-phenylenediamine in \( \text{H}_2\text{SO}_4 \) according to the method described by Sekiya et al. (1982) and Zhang et al. (2009), with some modifications. Leaves (0.5 g) were ground and extracted in 5 ml of phosphate buffer solution (pH 6.8, 50 mM) containing 0.1 M EDTA and 0.2 M ascorbic acid. The homogenate was mixed with 0.5 ml of 1 M HCl in a test tube to release \( \text{H}_2\text{S} \), and \( \text{H}_2\text{S} \) was absorbed in a 1% (w/v) zinc acetate (0.5 ml) trap which is located in the bottom of the test tube. After 30 min of reaction, 0.3 ml of 5 mM dimethyl-p-phenylenediamine dissolved in 3.5 mM \( \text{H}_2\text{SO}_4 \) was added to the trap. Then 0.3 ml of 50 mM ferric ammonium sulphate in 100 mM \( \text{H}_2\text{SO}_4 \) was injected into the trap. The amount of \( \text{H}_2\text{S} \) in zinc acetate traps was determined spectrophotometrically at 667 nm after leaving the mixture for 15 min at room temperature. Blanks were prepared by the same procedures without the zinc acetate solution.

Enzyme activity assays

RuBISCO (EC 4.1.1.39) was extracted according to Sayre et al. (1979) with slight modification. Spinacia oleracea leaves (10 g) were ground at 4 °C with a pestle in a mortar containing a small amount of quartz sand and 10 ml of grinding buffer solution consisting of 40 mM TRIS-\( \text{HCl} \) (pH 7.6), 10 mM \( \text{MgCl}_2 \), 0.25 mM EDTA, and 5 mM glutathione. After centrifugation at 20,000 g for 15 min at 4 °C, the supernatant was used for the enzyme assay. RuBISCO activity was assayed using the methods of Huang and Bie (2010). The activities of OAS-TL (EC 2.5.1.47) and LCD (EC 4.4.1.-) were determined as described by Bloem et al. (2004).

SDS–PAGE and western blot analysis

Leaf samples (0.5 g) were ground in liquid \( \text{N}_2 \) with a mortar and pestle. Total protein were extracted with a buffer containing 50 mM phosphate buffer solution (pH 7.5), 2% \( \beta \)-mercaptoethanol, 100 mM EDTA, 1% PVPP (w/v), and 1% Triton X-100 (v/v). After 15 min centrifugation (4 °C, 15,000 g), the upper phase was transferred to a new centrifuge tube. Two volumes of TRIS-saturated phenol (pH 8.0) were added and then the mixture was further vortexed for 30 min. Proteins were precipitated by adding 5 vols of ammonium sulphate-saturated methanol, and incubated at -20 °C for at least 4 h. After centrifugation as described above, the protein pellets were re-suspended and rinsed with ice-cold methanol followed by washing with ice-cold acetone twice, and spun down at 15,000 g for 10 min at 4 °C after each washing. Finally the washed pellets were air-dried and recovered in the lysis buffer containing 62.5 mM TRIS-\( \text{HCl} \) (pH 6.8), 2% SDS (w/v), 10% glycerol (v/v), and 2% \( \beta \)-mercaptoethanol (v/v). Protein concentrations were quantified using the Bradford assay (Bradford, 1976).

For western blot analysis, proteins (30 μg from each sample) were separated by SDS–PAGE using 12% (w/v) acrylamide gels according to Laemmli (1970) and electrophotographically transferred to a polyvinylidene difluoride (PVDF) membrane for 50 min. The membrane was blocked overnight with western blocking buffer (TIANGEN, China). The protein blot was probed with a primary antibody of the RuBISCO large subunit (AS03 037-200, Agrisera, Sweden) at a dilution of 1:5000 for 4 h at room temperature with agitation. Then the blot was washed three times in phosphate-buffered saline with Tween-20 (PBST) solution containing 50 mM TRIS-\( \text{HCl} \) (pH 8.0), 150 mM NaCl, 0.05% Tween-20 (v/v), and followed by incubation with the secondary antibody (anti-rabbit IgG horseradish peroxidase conjugated, Abcam, UK, 1:5000 dilution) for 2 h at room temperature. β-Actin (1:5000; Santa Cruz, CA, USA) was used as an internal control. The blots were finally washed as above and developed with SuperSignal West Pico Chemiluminescent Substrate (Pierce, USA) according to the manufacturer’s instructions. Images of the blots were obtained using a CCD imager (FluorSMax, Bio-Rad, USA). The Quantity One software (Bio-Rad, Hercules, CA, USA) was used to determine the optical density. The comparative optical density was used to determine the relative amount of protein expression, with the expression of β-actin used as an internal control.

Total RNA extraction and gene expression analysis

Quantitative real-time RT-PCR (qRT-PCR) was used to investigate the effect of \( \text{H}_2\text{S} \) on the expression patterns of genes encoding RuBISCO large subunit (RBCL), small subunit (RBCS), ferredoxin thioredoxin reductase (FTR), ferredoxin (FX), thioredoxin m (TRX-m), thioredoxin f (TRX-f), NADP-malate dehydrogenase (NADP-MDH), O-acetylsereine(thiol)lyase (OAS), serine acetyltransferase (SERAT), glycolate oxidase (GYX), and cytochrome oxidase (CCO) in S. oleracea seedlings. Leaves (0.5 g) were frozen and ground in liquid nitrogen with 2% polyvinylpyrrolidone and extracted with 0.5 ml of RNA purification reagent (Invitrogen Inc., CA, USA) by following the manufacturer’s procedure. The RNA concentration was determined by using an ultraviolet spectrophotometer (Cary 50, Varian, USA) and RNA integrity was detected by 1% agarose gel electrophoresis. Total RNAs were reverse-transcribed into first-strand cDNAs with an M-MLV reverse
transcriptase (TaKaRa, Dalian, China). A 10 μl real-time PCR contained the following: 0.6 μl of forward and reverse primers (Supplementary Table S1 available at JXB online; the concentrations were determined experimentally as suggested by the manufacturer), 1 μl of cDNA (equivalent to 10 ng of mRNA), and 5 μl of Faststart Universal SYBR Green Master (ROX, Mannheim, Germany). Amplification and detection of RBCL, RBCS, FTR, FRX, TRX-m, TRX-f, NADP-MDH, OAS, SERAT, GYX, and CCO double-stranded DNA (dsDNA) synthesis were performed using the PCR conditions as described in Supplementary Table S2. Three independent replicates were performed for each sample. The comparative threshold cycle (Ct) method was used to determine the relative amount of gene expression. The glyceraldehyde-3-phosphate dehydrogenase gene (GAPDH) was used as an internal control. The mRNA transcriptional abundance value of RBCL, RBCS, GYX, and CCO was expressed as 2−ΔΔCt (Livak and Schmittgen, 2001). The Rotor-gene-6000 Real-Time PCR system (Corbett Research, Mortlake, Australia) was used to run qRT-PCR.

Statistical analysis
For gas exchange and chlorophyll fluorescence measurements, at least six leaves were used. For physiological and biochemical analyses, at least three replicates were included. Statistical significance was tested by the one-way or two-way analysis of variance (ANOVA) procedure of SPSS 13.0 (SPSS Inc, Chicago, IL, USA), and results are expressed as the mean ± SE. Post-hoc comparisons were tested using the Tukey or t-test at a significance level of P < 0.05.

Results

**H₂S rather than other sulphur-containing derivatives causes the chlorophyll content increase in S. oleracea**

As the first step in investigating the role of H₂S in regulating plant photosynthesis, its effect on chlorophyll content in *S. oleracea* leaves was examined. In order to distinguish the role of H₂S from that of other sulphur-containing derivatives and sodium, a series of sulphur- and sodium-containing chemicals including NaHS, Na₂S, Na₂SO₃, Na₂SO₄, NaH₂SO₄, NaHSO₃, and NaAC were used to treat *S. oleracea* seedlings. After treatment for 30 d, Na⁺ or other sulphur-containing compounds, which were used as controls of NaHS, did not cause as great an increase in chlorophyll content as NaHS (Fig. 1A). It was also observed that the leaf chlorophyll content of seedlings treated with 100 μM NaHS was much higher than that of other treatments. Furthermore, the H₂S generated from various chemicals was detected by a selective H₂S sensor (Fig. 1B). Consistently, it was found the H₂S generated from 100 μM NaHS was the highest among the chemicals. These results suggest that H₂S rather than other sulphur-containing compounds or sodium was responsible for the increase in chlorophyll content in *S. oleracea* after NaHS treatment. Therefore, NaHS was used as a donor of H₂S in the subsequent experiments.

**Effects of NaHS on seedling growth and chlorophyll content of *S. oleracea***

Chlorophyll was measured as a parameter of photosynthesis. Figure 2A showed that NaHS at lower concentrations enhanced seedling growth, with 100 μM being the optimal concentration. Figure 2B also showed that the biomass reached a maximum under 100 μM NaHS treatment, which was ~2.6-fold higher than that of the control and a 146% increase as compared with the 10 μM NaHS treatment. In contrast, the biomass decreased by 55% and 37% at 500 μM and 1000 μM NaHS, respectively, compared with the control. Leaf soluble protein content exhibited a pronounced increase in various NaHS-treated seedlings compared with the untreated control (Fig. 2C). Figure 1 clearly shows that H₂S rather than other sulphur-containing derivatives enhances chlorophyll content. Here, the dose effect of NaHS on chlorophyll content was also explored. Figure 2D revealed that the chlorophyll content and chl *ab* reached their maximum under 100 μM NaHS treatment, with an ~2.2- and 1.2-fold increase as compared with the control. Based on the above results, 100 μM is the optimal concentration for NaHS-induced seedling growth and chlorophyll accumulation; higher concentration of NaHS could be toxic for plant growth as reflected by the results in Fig. 2A and B.

**Effect of NaHS on chloroplast ultrastructure**

To evaluate further the role of NaHS in photosynthesis, transmission electron microscopy was used to analyse the changes in ultrastructure of chloroplasts after the application of NaHS. It was found that the number of grana lamellae stacking into functional chloroplasts significantly increased in leaves of 100 μM NaHS-treated seedlings compared with the control or 10 μM NaHS-treated seedlings (Fig. 3A, C). In contrast, under 1000 μM NaHS treatment, the number of grana lamellae stacking into functional chloroplasts was obviously decreased compared with 100 μM NaHS-treated leaves (Fig. 3D). These results suggest that 100 μM NaHS has a promoting effect and higher concentrations have inhibiting effects on the number of grana lamellae stacking into functional chloroplasts in *S. oleracea*.

![Figure 1](image-url)
Effects of NaHS on the photosynthetic rate and chlorophyll fluorescence of S. oleracea leaves

In order to investigate the effect of NaHS on seedling photosynthetic characteristics further, $P_n$ and $g_s$ of leaves were measured at 800 μmol m$^{-2}$ s$^{-1}$ PAR with treatments using different NaHS concentrations. $P_n$ and $g_s$ reached a maximum under 100 μM NaHS treatment (Fig. 4A). Further, light–response curves and CO$_2$–response curves indicated that $P_n$ was obviously higher in NaHS-treated seedlings than in the control (Fig. 4C, D). Chlorophyll fluorescence measurements showed that $F_{v}/F_{m}$ and $F_{v}/F_{o}$ were much higher in the NaHS-treated seedlings than in the control (Fig. 4B). In addition, the $R_d$, $L_{cp}$, $L_{sp}$, $AQE$, and $P_{max}$ of seedlings were calculated by modelling the response of leaf $P_n$ to PAR by a non-rectangular hyperbola and the $CE$ was acquired by a rectangular hyperbola (Table 1). No effect of donor NaHS on $AQE$ was found. However, $R_d$ and $L_{cp}$ were lower under NaHS treatment than in the control, whereas $P_{max}$, $L_{sp}$, and $CE$ were notably higher under NaHS treatment. All these results suggest that seedling photosynthetic characteristics were significantly affected by 100 μM NaHS treatment.

Effects of NaHS on RuBISCO activity and RuBISCO LSU protein expression

In order to clarify the mechanism of H$_2$S-enhanced photosynthesis biochemically, the effects of different NaHS concentrations on the expression of RuBISCO LSU were analysed by protein western analysis. As shown in Fig. 5A and B, after quantification and normalization to β-actin, the protein expression level of RuBISCO LSU reached the maximal values under 10 μM and 100 μM NaHS treatments, which were 1.6- and 1.58-fold higher than the control, respectively. These data suggest that H$_2$S enhanced photosynthesis probably through up-regulating the protein expression of RuBISCO LSU. In addition, there was a significant increase in RuBISCO activity in response to 10 μM and 100 μM NaHS treatment (Fig. 5C). In brief, the H$_2$S-enhanced photosynthesis may be attributed to the increased protein expression of RuBISCO LSU and improved RuBISCO activity in a certain range of NaHS concentrations.
Effects of NaHS on RBCL and RBCS gene expression

To evaluate further the molecular response of *S. oleracea* photosynthesis to H$_2$S, the genes encoding the RuBISCO large and small subunits were analysed at the transcriptional level using qRT-PCR. The expression of RBCL and RBCS was normalized by using GADPH as a reference gene. Figure 6A showed that the relative gene expression abundance of RBCL in leaves of *S. oleracea* treated with 10 lM and 100 lM NaHS was higher than in the control (0 lM NaHS). Figure 6B and C showed the time course change of RBCL and RBCS expression in leaves of *S. oleracea* treated with 100 lM NaHS for 0, 6, 12, 24, and 36 h. The RBCL expression reached the maximal value at 24 h of NaHS treatment, being 1.91-fold higher than that of the control (0 h) (Fig. 6B). Similarly, the RBCS expression was also increased by 158% at 36 h of NaHS treatment compared with the control (0 h) (Fig. 6C).

Effects of NaHS on thiol content and gene expression related to thiol redox modification

To study further whether exogenously applied NaHS has an effect on thiol redox modification of proteins involved in photosynthesis, the total NPTs, GSH, and cysteine content was measured. As shown in Table 2, NaHS treatment resulted in an obvious increase in thiol content. Moreover, the expression of genes related to thiol redox modification in chloroplasts including FTR, FRX, TRX-m, TRX-f, and NADP-MDH was also obviously increased under NaHS treatment (Fig. 7A–E).

Effects of NaHS on endogenous H$_2$S production

A high accumulation of endogenous H$_2$S in *S. oleracea* seedling leaves caused by exogenously applied NaHS was observed (Table 2). To evaluate further the role of NaHS in sulphide metabolism in plant, the activity of several key enzymes in sulphide metabolism was measured. As shown in Table 2, the activities of OAS-TL and LCD were increased by NaHS treatment. Further, the expression of OAS and SERAT genes encoding OAS-TL and serine acetyltransferas (SAT), respectively, was measured in *S. oleracea* treated with NaHS. As shown in Fig. 7F and G, the expression abundance of OAS was obviously increased under NaHS treatment, whereas that of SERAT was reduced.
Effects of NaHS on GYX and CCO gene expression

Based on the above photosynthesis data related to \( R_d \) and \( L_c p \), the gene expression of \( G Y X \) and \( C C O \) in \( S. \ oleracea \) seedlings treated with the optimal NaHS concentration was further analysed. As shown in Fig. 7H and I, the relative expression abundance of \( G Y X \) and \( C C O \) was significantly decreased under NaHS treatment compared with the control, suggesting that the light and dark respiration could be reduced by the given concentration of NaHS.

Discussion

\( H_2S \) affected chlorophyll content, plant growth, and chloroplast ultrastructure

NaHS has been widely used as an \( H_2S \) donor in animal research (Hosoki et al., 1997). It dissolves in water and dissociates to produce \( Na^+ \) and \( HS^- \), then \( HS^- \) associates with \( H^+ \) to form \( H_2S \). In this report, other sulphur-containing components such as \( S^{2-} \), \( SO_3^- \), \( SO_3^{2-} \), \( HSO_4^- \), and \( S_2O_3^{2-} \) were also detected in the cell extracts of \( S. \ oleracea \) seedlings treated with NaHS. The effects of NaHS on the expression of \( RBCL \) and \( RBCS \) were investigated in the present study. The results showed that NaHS could significantly increase the relative mRNA level of \( RBCL \) and \( RBCS \) compared with the control, suggesting that \( H_2S \) could positively regulate the expression of these genes.

Table 2. Effects of the \( H_2S \) donor NaHS on non-protein thiols (NPTs), glutathione (GSH), cysteine, endogenous \( H_2S \) content, O-acetylserine(thiol)lyase (OAS-TL), and L-cysteine desulphydrase (LCD) activities of \( S. \ oleracea \) seedlings

| Variables                          | Control   | 100 \( \mu \)M NaHS |
|------------------------------------|-----------|---------------------|
| NPTs (\( \mu \)mol g\(^{-1}\) FW)  | 2.69±0.03 | 4.47±0.23**         |
| GSH (nmol g\(^{-1}\) FW)           | 221.6±5.8 | 360.5±31.9*        |
| Cysteine (nmol g\(^{-1}\) FW)      | 6.46±0.53 | 8.55±0.18*         |
| Endogenous \( H_2S \) content (\( \mu \)mol g\(^{-1}\) FW) | 0.041±0.007 | 0.107±0.015**    |
| OAS-TL (nmol Cys mg\(^{-1}\) protein min\(^{-1}\)) | 609.9±26.7 | 724.4±20.7*    |
| LCD (nmol H\(_2\)S mg\(^{-1}\) protein min\(^{-1}\)) | 22.38±0.74 | 28.36±0.96*    |
HSO₃⁻ and Na⁺ were used as the controls of NaHS, but none of them was able to increase the chlorophyll content of *S. oleracea* (Fig. 1A). Meanwhile, in order to understand the actual H₂S generation from these chemicals used, the H₂S generation by various sulphur-containing chemicals was directly analysed using a selective H₂S sensor (Fig. 1B). It was found that the H₂S generated from NaHS was the highest among all the chemicals tested under the same measuring conditions including pH, temperature, time, volume, solution, and so on. Although Na₂S also generated H₂S, it was not steady within the measurement period used here (Supplementary Fig. S2 at JXB online). Furthermore, NaHS promoted the chlorophyll content, photosynthesis, and growth of *S. oleracea* in a dose-dependent manner (Figs 2A, 4; Table 1), which is consistent with the observations by other researchers that H₂S affected chlorophyll content and enhanced the embryo root length of *Pisum sativum* (Zhang et al., 2009; Li et al., 2010). It is well known that the chlorophyll content and photosynthetic rate are closely correlated in plants. The result implies that H₂S may play an important role in promoting photosynthesis in *S. oleracea*.

In animal cells, low concentrations of H₂S have been proven to function as a signalling molecule (Wang, 2002). Therefore, it is important to clarify whether H₂S also plays a role in modulating physiological processes in plants. Recently, it was demonstrated that H₂S may act as an antioxidant to counteract oxidative stresses induced by copper, boron, and aluminium toxicity (Zhang et al., 2008, 2010; Wang et al., 2010) as well as osmotic stress in plants (Zhang et al., 2009). In addition, a recent report demonstrated that H₂S induces stomatal closure and participates in the abscisic acid (ABA)-dependent signalling pathway by regulating ATP-binding cassette (ABC) transporters in guard cells (García-Mata and Lamattina 2010). In the present study, it was revealed that 100 µM NaHS increased seedling biomass, and soluble protein and chlorophyll content in *S. oleracea*. However, a high NaHS concentration decreased these parameters (Fig. 2). In addition, the number of grana lamellae in functional chloroplasts was

Fig. 7. Effects of H₂S on ferredoxin thioredoxin reductase (FTR) (A), ferredoxin (FRX) (B), thioredoxin m (TRX-m) (C), thioredoxin f (TRX-f) (D), NADP-malate dehydrogenase (NADP-MDH) (E), O-acetylserine(thiol)lyase (OAS) (F), serine acetyltransferase (SERAT) (G), glycolate oxidase (GYX) (H), and cytochrome oxidase (CCO) (I) gene expression in *Spinacia oleracea* seedlings treated with 100 µM NaHS in half-strength Hoagland’s nutrient solution. The relative mRNA level of each gene was normalized to the mRNA of GADPH. Data are presented as the mean ± SE of three replicates. The significant level of difference between control and treatment is indicated by *, ** and *** for *P* < 0.05, *P* < 0.01 and *P* < 0.001, respectively.
also significantly increased by 100 μM NaHS treatment compared with the control and other NaHS concentrations (Fig. 3A, C). These results suggest that 100 μM NaHS could promote the biogenesis of chloroplasts by increasing the number of grana lamellae and the biosynthesis of chlorophyll, which will lead to an enhancement of photosynthesis.

\[ \text{H}_2 \text{S affected photosynthetic characteristics in S. oleracea} \]

The function of a low concentration of H\(_2\)S in plant photosynthesis is still not clear. Data from the present experiments showed that H\(_2\)S may be involved in the regulation of photosynthesis as 100 μM NaHS enhances while a higher concentration inhibits the photosynthesis of *S. oleracea* (Fig. 4A). These results are in accordance with the data from previous studies showing that excess H\(_2\)S negatively affects plant growth by inhibiting mitochondrial electron transport and photosynthesis in plants (Beauchamp *et al.*, 1984; Lin and Sternberg, 1992).

Further analysis on photosynthetic features revealed that *Pn* reached maximum values under 100 μM NaHS treatment compared with the control and treatments with other NaHS concentrations (Fig. 4A, D). *Pmax* was also significantly higher in NaHS-treated seedlings than in the control (Table 1). This result is important for clarifying the effect of H\(_2\)S on photosynthesis because a higher *Pmax* allows seedlings to acquire a higher potential to assimilate carbon dioxide. *AQE* reflects the light use efficiency of plants at low light intensities. No significant difference in *AQE* between the control and 100 μM NaHS-treated plants was observed, suggesting that NaHS treatment could not enhance the light use efficiency of *S. oleracea* at a lower light intensity. *Lsp* represents the capacity of plants to use the maximal light. The results showed that 100 μM NaHS can enhance the maximal light use of *S. oleracea* under a high light intensity. On the other hand, as *Lcp* is the light value at which the rate of CO\(_2\) fixation by photosynthesis is equal to the rate of CO\(_2\) release by respiration and photorespiration, a lower *Lcp* reflects a lower respiration and a higher RuBISCO carboxylase activity or lower RuBISCO oxygenase activity (Nunes *et al.*, 2009). Some studies have reported that a sharp increase in *Lcp* can be induced by drought, water deficit, and infective disease (Shen *et al.*, 2007; Nunes *et al.*, 2009). The obvious decrease in *Lcp* in 100 μM NaHS-treated seedlings observed in the present study (Table 1) implies that NaHS could enhance photosynthesis and the accumulation of organic compounds in *S. oleracea* seedlings. In addition, the sharp decrease in *Rd* under 100 μM NaHS (Table 1) indicates that NaHS-treated *S. oleracea* seedling had lower respiration compared with the control. As cytochrome oxidase is the terminal oxidase in respiration and glycolate oxidase is the first enzyme in photorespiration, the changes in the mRNA expression of these enzymes were analysed by qRT-PCR (Fig. 7H, I). The results showed that the mRNA expression of these two enzymes was inhibited significantly by 100 μM NaHS treatment. These findings allow the conclusion to be reached that the decrease in *Rd* by H\(_2\)S may be due to the decrease of the cytochrome oxidase level. This hypothesis is in agreement with a previous study which suggested that the mitochondria cytochrome oxidase activity was obviously inhibited by H\(_2\)S as well as NO and CO in mammalian cells (Cooper and Brown, 2008).

In plant responses to changed environment or external signals, leaf photosynthesis is often altered due to changes in *g_\text{s}* and/or *CE* in mesophyll cells (Yuan and Xu, 2001). In the present study, the increases in *Pn* and *CE* of *S. oleracea* leaves caused by 100 μM NaHS (Fig. 4A; Table 1) can be explained by both the increased *g_\text{s}* and the H\(_2\)S-induced enhancement in the carboxylation process, as the enhancement of *CE* has been considered to play a major role in the improvement of photosynthesis (Pell *et al.*, 1992; Farage and Long, 1999).

**Changes of photochemical efficiency**

Chlorophyll fluorescence is a measure of PSII function and light harvesting efficiency. The *F/\text{Fm}* in dark-adapted leaves is recognized as a good indicator of a photo-inhibitory or photo-oxidative effect on PSII (Maxwell and Johnson, 2000). The *F/\text{Fm}* and *F/\text{Fo}* increased significantly in *S. oleracea* treated with 100 μM NaHS (Fig. 4B), indicating that the photochemical reaction in PSII was partially increased, which is consistent with the increase in chlorophyll content caused by 100 μM NaHS treatment (Fig. 2D). Chlorophyll contributes greatly to the light harvesting and primary photochemical reaction in plants (Yan *et al.*, 2010) and chlorophyll content correlates closely to the *F/\text{Fm}* and *F/\text{Fo}* in agreement with a previous study showing that excess sulphide (1 mM) inhibited the activity of PSII in cyanobacteria and tobacco chloroplasts (Oren *et al.*, 1979), the present results also indicated that a high concentration of sulphide has harmful effects on PSII in plants.

**Changes in enzyme activity and gene expression of RuBISCO**

RuBISCO is a key enzyme controlling photosynthetic carbon fixation in plants, and the level of activated RuBISCO is closely related to the *Lsp*, *CE*, and the rate of photosynthetic carbon assimilation (Seemann and Berry, 1982; Lin and Hsu, 2004). The present results showed that the protein expression of RuBISCO LSU reached the highest level under 10 μM and 100 μM NaHS (Fig. 5A, B). Meanwhile, a significant increase in RuBISCO activity was observed at 100 μM NaHS treatment (Fig. 5C), suggesting that the improvement in photosynthesis under 100 μM NaHS treatment was a result of an increase in RuBISCO level.

To evaluate further the molecular effect of the H\(_2\)S donor NaHS on photosynthesis of *S. oleracea*, the changes at the transcriptional level of *RBCL* and *RBCS* were investigated using qRT-PCR. The results showed that the expression of *RBCL* and *RBCS* was significantly up-regulated by 100 μM
NaHS even within a short time (Fig. 6A–C), suggesting that RuBISCO biosynthesis is very sensitive to H2S treatment. Taken together, all the evidence presented here indicates that the positive effect of 100 μM NaHS on leaf photosynthesis occurs mainly through stimulating the transcription of RBCL and RBCS mRNA and enhancing the accumulation and activity of RuBISCO.

NaHS treatment causes changes in the level of total thiols and gene expression related to thiol redox modification

Previous studies have shown that in plants treated with H2S, H2S is rapidly incorporated into organic sulphur compounds, resulting in an increase in soluble thiols including GSH and cysteine (Schutz et al., 1991). In the present study, it was found that the NPTs, GSH, and cysteine contents were significantly increased in S. oleracea after treatment with the optimal concentration of NaHS. Miginiac-Maslow et al. (2000) addressed the importance of thiol redox modification in photosynthetic electron transfer. It is well known that the ferredoxin/thioredoxin system in chloroplasts is critical for regulation of CO2 assimilation in oxygenic photosynthesis (Buchanan, 1991). The ferredoxin/thioredoxin system, consisting of ferredoxin, ferredoxin-thioredoxin reductase (FTR), and thioredoxin (m and f), is a general mechanism of light-mediated enzyme regulation (Buchanan, 1991). Ferredoxin is reduced in the light by photosynthetic electron transfer at the level of PSI. It reduces FTR, generating a dithiol that reduces the disulphide bridge of thioredoxin. The very reactive dithiol of reduced thioredoxin m (named for its effectiveness in NADP-MDH activation) and f (named for its effectiveness in fructose-1,6-bisphosphatase (FBPase) activation) reduces the disulfides of NADP-MDH and FBPase, respectively, which shifts from a totally inactive to a fully active form (Ramaswamy et al., 1999). In the present study, the gene expression of proteins in the ferredoxin/thioredoxin system, including ferredoxin, FTR, and thioredoxin (m and f), was obviously increased due to the higher content of thiols (Fig. 7A–D and Table 2), and the expression of NADP-MDH, which is strictly regulated by light through the ferredoxin/thioredoxin system, was also significantly increased under NaHS treatment (Fig. 7E). Since the ferredoxin/thioredoxin system in chloroplasts is quite important for regulation of CO2 assimilation in oxygenic photosynthesis (Buchanan, 1991), the data led to the conclusion that H2S not only functions as a signalling molecule, but is also involved in thiol redox modification to impact on the photosynthetic CO2 assimilation in S. oleracea.

Endogenous H2S production in NaHS-treated S. oleracea

In this study, the externally applied NaHS led to an increase in the internal concentration of H2S in S. oleracea leaves (Table 2), which is similar to the results observed by other researchers (Zhang et al., 2008, 2010). Further enzymatic analyses indicated that the externally applied NaHS significantly enhanced the activity of OAS-TL but only slightly enhanced that of the LCD enzyme (Table 2). Consistent with this, qRT-PCR experiments revealed that the expression of the OAS gene was significantly enhanced by the NaHS treatment (Fig. 7F), but not that of the SERAT gene (Fig. 7G). Since OAS-TL and LCD are responsible for H2S release, and OAS-TL, LCD, and SAT control the cysteine levels in plants (Riemenschneider et al., 2005), the NaHS-induced increase in the cysteine and H2S levels in the present study could be largely due to the enhancement of the OAS-TL enzyme activity and gene expression instead of that of LCD and SAT. Therefore, the results suggest that externally supplied NaHS is also involved in sulphide metabolism.

In summary, the present results indicated that the increase in net leaf photosynthesis caused by 100 μM NaHS is mainly due to the enhanced expression and activity of RuBISCO and proteins involved in thiol redox modification. In addition, Pmax, CE, gs, Lsp, and Fv/Fm were all obviously increased by 100 μM NaHS treatment, which will further enhance photosynthesis. Finally, 100 μM NaHS treatment resulted in a significant increase in plant biomass, chlorophyll content, soluble protein content, and the number of grana lamellae in chloroplasts. Taken together, these findings highlight an important role for H2S in regulating leaf photosynthesis by possibly increasing the quantity and activity of RuBISCO, enhancing photosynthetic electron transfer through thiol redox modification, improving chloroplast biogenesis, etc. Further studies are needed to clarify the other photosynthetic processes affected by H2S and to dissect the signaling pathways by which H2S mediates the photosynthesis enhancement.

Supplementary data

Supplementary data are available at JXB online.

Figure S1. Electrochemical detection of H2S concentration performed under various NaHS concentrations using an H2S-selective electrode.
