(Dated: July 15, 2018)

We use the uniform semiclassical approximation in order to derive the fidelity decay in the regime of large perturbations. Numerical computations are presented which agree with our theoretical predictions. Moreover, our theory allows us to explain previous findings, such as the deviation from the Lyapunov decay rate in cases where the classical finite-time instability is nonuniform in phase space.

PACS numbers: 05.45.Mt, 05.45.Pq, 03.65.Sq

The stability of quantum motion under a system’s perturbation can be measured by the so-called quantum Loschmidt echo or fidelity \[1, 2, 3\]. It is defined as the overlap \(M(t) = |\langle \Psi(t) | \Psi(0) \rangle|^2\) of two states obtained by evolving the same initial state \(|\Psi(0)\rangle\) under two slightly different Hamiltonians:

\[ m(t) = \langle \Psi(0) | \exp(iHt/\hbar) \exp(-iH_{0}t/\hbar) | \Psi(0) \rangle. \quad (1) \]

Here \(H_{0}\) is the Hamiltonian of a classically chaotic system and \(H = H_{0} + \epsilon V\) is the perturbed Hamiltonian, with \(\epsilon\) a small quantity and \(V\) a generic perturbing potential. This quantity can also be seen as a measure of the accuracy to which an initial quantum state can be recovered by inverting, at time \(t\), the dynamics with the perturbed Hamiltonian \(H\).

This quantity has attracted much attention recently, mainly in relation to the field of quantum computation and in connection to the corresponding classical motion \[4, 5, 6, 7, 8, 9, 10, 11, 12, 13\]. Focusing on systems with chaotic classical limit, one may identify, by increasing the perturbation strength, three different regimes of fidelity decay: (i) The perturbative regime, in which the fidelity has a Gaussian decay. (ii) The Fermi-golden-rule regime, with an exponential decay of fidelity, \(M(t) \propto \exp(-\Gamma t)\). Here the decay rate \(\Gamma\) is the half-width of the local spectral density of states (LDOS) \[2\], which can also be calculated semiclassically \[3\]. (iii) The Lyapunov regime, in which \(M(t) \propto \exp(\lambda t)\), with \(\lambda\) being the (maximum) Lyapunov exponent of the underlying classical dynamics \[4\].

However, the above picture remains unsatisfactory. This is particularly the case in the deep Lyapunov regime with \(\sigma \gg 1\), where \(\sigma = \epsilon/\hbar\) is the parameter characterizing the strength of quantum perturbation, and \(\hbar\) the (effective) Planck constant. In systems with nonconstant finite-time Lyapunov exponent (which is the typical situation), fidelity decays with a rate different from \(\lambda\) \[11\]. Indeed, a semiclassical analysis \[11\] leads to an exponential decay of fidelity with a rate \(\lambda_{1} < \lambda\). The relation between this semiclassical treatment and that along the lines of Refs. \[1, 2, 12, 13\] is unclear. Moreover, an extremely fast, super-exponential decay of fidelity has been found within a quite short initial time for initial Gaussian wave packets \[11\]. In view of the importance of fidelity for the characterization of the stability of quantum motion under a system’s perturbation, it is necessary to provide a clear theoretical understanding of its behavior and, in particular, to account for the seemingly disconnected and sometimes contradictory results.

In this paper, we focus on the behavior of fidelity for \(\sigma \gg 1\) and we treat this problem in full generality. We derive the general semiclassical formula which correctly reproduces the two limiting cases of \(\exp(-\lambda t)\) and \(\exp(-\lambda_{1} t)\) decays. We also show that under certain conditions the exponential rate of fidelity decay can be equal to twice the classical Lyapunov exponent.

Our starting point is the semiclassical approximation to the fidelity for an initial Gaussian wave packet given in \[12\]:

\[ m_{sc}(t) \simeq \left( \frac{\xi^{2}}{\pi \hbar^{2}} \right)^{d/2} \times \int dp_{0} \exp \left[ i \Delta S(p_{0}, r_{0}; t)/\hbar - \left( p_{0} - \tilde{p}_{0} \right)^{2} / (\hbar/\xi)^{2} \right], \quad (2) \]

where \(\Delta S(p_{0}, r_{0}; t)\) is the action difference along the two nearby trajectories starting at \((p_{0}, r_{0})\) in the two systems \(H\) and \(H_{0}\),

\[ \Delta S(p_{0}, r_{0}; t) \simeq \epsilon \int_{0}^{t} dt' V[r'(t')] \] (3)

with \(V\) evaluated along the trajectory in the \(H_{0}\) system. The initial Gaussian wave packet, centered at \((\tilde{r}_{0}, \tilde{p}_{0})\), is

\[ \psi_{0}(r_{0}) = \left( \pi \xi^{2} \right)^{-d/4} \exp \left[ i \tilde{p}_{0} \cdot r_{0} / \hbar - (r_{0} - \tilde{r}_{0})^{2} / (2\xi^{2}) \right]. \quad (4) \]
For simplicity, we will consider here kicked systems with $d = 1$ and set the domains of $r$ and $p$ to be $[0, 2\pi]$. The effective Planck constant is taken as $\hbar = 2\pi/N$, where $N$ is the dimension of the Hilbert space.

The main feature of $\Delta S$ as a function of $p_0$ is its oscillations, the number of which increases exponentially with time $t$. Indeed, the variance of $\Delta S$ increases linearly with $t$ [2], while the slope of $\Delta S/\epsilon$, denoted by $k_p$, 

$$k_p = \frac{1}{\epsilon} \frac{\partial \Delta S(p_0, r_0; t)}{\partial p_0} \approx \int_0^t dt' \frac{\partial V}{\partial r'} \frac{\partial r'}{\partial p_0},$$

increases on average exponentially with $t$, due to the factor $\partial r'/\partial p_0$.

Let us first discuss the fidelity for a single initial state. Neglecting a quite short initial time, the main contribution to the right hand side of Eq. [2] comes from the integration over the region $[\bar{p}_0 - w_p, \bar{p}_0 + w_p]$, where $w_p = \hbar/\xi$ is the width of the initial Gaussian in the $p_0$ space. Let us define a time scale $\tau$ such that at $t = \tau$, $\Delta S(p_0, r_0; t)$ completes one full oscillation period as $p_0$ runs over $[\bar{p}_0 - w_p, \bar{p}_0 + w_p]$. In a system possessing a constant local Lyapunov exponent $\lambda$, the number of oscillations of $\Delta S$ increases exponentially as $e^{\lambda t}$ and we obtain the average estimate for $\tau$,

$$\tau \approx \frac{1}{\lambda} \ln(\pi/\epsilon_0 w_p).$$

(6)

Taking, e.g., $\xi = \sqrt{\hbar}$, one can clearly see that $\tau$ is of the order of the Ehrenfest time $\frac{1}{\lambda} \ln \hbar^{-1}$. In the general case of systems with fluctuation in the finite-time Lyapunov exponent, the number of the oscillations of $\Delta S$ increases exponentially as $e^{\Lambda(t)}$, with some time-dependent rate $\Lambda(t) < \lambda$.

We consider first the behavior of fidelity for $t < \tau$ and denote with $k_p^*$ the value of $k_p$ in the center $(\bar{p}_0, \bar{r}_0)$ of the initial Gaussian. For such times, the phase $\Delta S/\hbar$, on the right hand side of Eq. [2], as a function of $p_0$, can usually be approximated by a straight line with a slope $\sigma k_p^*$, within the region $p_0 \in [\bar{p}_0 - w_p, \bar{p}_0 + w_p]$. Due to both the fast increasing of $|k_p|$ with time and the large $\sigma$ value, one has $|\sigma k_p^*| \gg \pi/w_p$ for most initial times and, as a result, the change of the phase $\Delta S/\hbar$ within the interval $p_0 \in [\bar{p}_0 - w_p, \bar{p}_0 + w_p]$ is much larger than $2\pi$. Note that the largest slope of the term $(p_0 - \bar{p}_0)^2/2\hbar^2$ within this interval of $p_0$ is $2/w_p$, which is much smaller than $|\sigma k_p^*|$. The right hand side of Eq. [2] can now be calculated approximately within the interval $p_0 \in [\bar{p}_0 - w_p, \bar{p}_0 + w_p]$ and gives

$$M_{sc}(t) \propto \frac{1}{(\sigma k_p^*)^2}.$$

(7)

For times $t > \tau$, or when $|k_p|$ is small enough for $t < \tau$, the stationary phase approximation can be used in calculating $M_{sc}(t)$ in Eq. [2]. If we denote by $\alpha$ the stationary points and by $p_{0\alpha}$ the momenta at which $k_p = 0$, we have

$$m_{sc}(t) \simeq \sum_{\alpha} m_\alpha(t),$$

where

$$m_\alpha(t) = \frac{1}{w_p} \frac{\sqrt{2\pi} \hbar}{\sqrt{|\Delta S'_\alpha|}} \exp \left[ \frac{1}{4} \Delta S(p_{0\alpha}, \bar{r}_0; t) - (p_{0\alpha} - \bar{p}_0)^2/w_p^2 \right].$$

(8)

The right hand side of Eq. [9] can be expressed as an integration of $1/|k_p|$. For this, we introduce $A_n$ to denote the region $[p_{0\alpha}, p_{0\alpha} - \delta] \cup [p_{0\alpha} + \delta, p_{0\alpha}]$, where $p_{0\alpha} = (p_{0\alpha} + p_{0\alpha} - 1/2, p_{0\alpha} = (p_{0\alpha} + p_{0\alpha} + 1)/2$, and where $\delta$ is a small quantity. In the neighborhood of $p_{0\alpha}$, $k_p$ satisfies $ck_p \simeq \Delta S''_\alpha(p_0 - \bar{p}_0)$. For small enough $\delta$, we have

$$\int_{A_n} dp_0 \frac{1}{|k_p|} \simeq \frac{2 \ln \delta}{|\Delta S''_\alpha|}.$$  

(10)

Substituting the expression of $|\Delta S''_\alpha|$ obtained from

![FIG. 1: Decay of averaged fidelity in the map (10), with $K = 1$, $\eta = 0.987$. $I_s$ and $I_A$ are the theoretical predictions and experimental data, respectively. It is seen that after a short initial time, both $I_s(t)$ and $I_A(t)$ are close to the exact fidelity $M(t)$ (until saturation is reached). For comparison, the decay $e^{-\lambda_1 t}$ is shown. We also plot the average classical fidelity, which was calculated by taking initial points within circles with radius $\sqrt{\hbar}$ in the phase space $\mathbb{R}^2$. For this map, $\Lambda \approx 0.9$ and $\lambda_1 \approx 0.35$. Here and in the following figures, $\sigma = 100$, $N = 131072$, $\xi = \sqrt{\hbar}$, and averages are performed over 2000 initial Gaussian packets.](image)
Eq. (10) into Eq. (9), we have

$$M(t) \approx \frac{\xi}{(2\pi)^{3/2}(-2\ln \delta)e} \int_0^{2\pi} d\tilde{r}_0 \int_{|k_p|} dp_0 \frac{1}{|k_p|},$$

(11)

where $P_\delta := \bigcup_n A_n$.

Since the value of $\delta$ is irrelevant for the decay rate, we may write

$$M(t) \propto I_s(t) := \int d\tilde{r}_0 \int_{|k_p|} dp_0 \frac{1}{|k_p|},$$

(12)

An accurate numerical evaluation of $I_s(t)$ is not easy since one must find out all stationary points $\alpha$ for each value of $\tilde{r}_0$. An approximate numerical result can be obtained by using the Monte Carlo method in which, in order to perform the integral over the region $P_\delta$, i.e., with the neighborhoods of stationary points excluded, we neglect the small set of points that have the smallest values of $|k_p|$.

Actually, one can make a further approximation by using the following arguments. The main contribution to the integral in Eq. (11) comes from small values of $|k_p|$ in the region $P_\delta$. For $p_0 \in P_\delta$ close to a stationary point $p_{\alpha}$, $k_p$ in Eq. (12) can be approximated by

$$k_p \approx \int_0^t dt' \left[ \frac{\partial^2 V}{\partial r' \partial \tilde{r}_0} \left( \frac{\partial \tilde{r}_0}{\partial p_0} \right)^2 + \frac{\partial V}{\partial \tilde{r}_0} \frac{\partial^2 \tilde{r}_0}{\partial \tilde{r}_0^2} \right] (p_0 - p_{\alpha}).$$

(13)

Due to exponential divergence of neighboring trajectories in phase space, the main contribution to the right hand side of Eq. (13) comes from times $t' \approx t$. The time evolution of the quantity inside the bracket in Eq. (13) is given by the dynamics of the system described by $H_0$. On average it increases as $[\delta x(t)/\delta x(0)]^2$, where $\delta(x)$ denotes distance in phase space. With increasing time, the number of the stationary points of $\Delta S$ increases exponentially, roughly in the same way as $\delta x(t)/\delta x(0)$, since the oscillation of $\Delta S$ is mainly induced by local instability of trajectories. Then, substituting Eq. (13) into Eq. (11), we have $M(t) \propto |\delta x(t)/\delta x(0)|^{-1}$, which can be written as

$$M(t) \propto I_\lambda(t) = \exp[-\Lambda_1(t)t],$$

(14)

with

$$\Lambda_1(t) = -\frac{1}{t} \lim_{\delta x(0) \to 0} \ln \left| \frac{\delta x(t)}{\delta x(0)} \right|^{-1}.$$
it acquires a marginally stable (parabolic) fixed point. This map is quantized in a Hilbert space of dimension $N$. The one period quantum evolution is given by the Floquet operator, $U = \exp[-i\tilde{p}^2/(2\hbar)]\exp[-i\tilde{H}(\tilde{p})/\hbar]$, with $U(\tau) = -K[(r-\pi)^2/2 - \eta \cos r]$. In order to compute fidelity, we choose to perturb the parameter $K \to K + \epsilon$.

Figure 4 shows numerical data accurately fit our theoretical predictions in Eqs. (12) and (14). In Fig. 4, it is seen that with decreasing $\eta$, since the values of $\lambda$ and $\lambda_i$ become closer, our predictions approach that of Ref. [11]. At $\eta = 0$, the classical map has a constant local Lyapunov exponent and the standard Lyapunov decay is recovered.

In the above discussion of the average fidelity, the existence of stationary phase is assumed. It may happen, in some circumstance, e.g., with some special perturbation, that there is no stationary phase for $\Delta S$. In this case it turns out that a decay with a rate of double Lyapunov exponent may appear for $t < \tau$, when the classical system has a constant local Lyapunov exponent. Indeed, for $t < \tau$, the main contribution to the averaged fidelity $\langle M(t) \rangle$ comes from initial states for which the values of $|k_p|$ are close to local minimum of $|k_p|$. When the values of local minimum of $|k_p|$ are large enough, the decay of the fidelity is given by Eq. (17). Then, since $|k_p|$ increases on average as $e^{\lambda t}$, the averaged fidelity has a double-Lyapunov-exponent decay,

$$\langle M(t) \rangle \propto e^{-2\lambda t}, \quad t < \tau.$$  

For $t > \tau$, one can use arguments given in Ref. [11], showing that $\langle M(t) \rangle$ still follows the standard Lyapunov decay, $\langle M(t) \rangle \propto e^{-\lambda t}$.

Finally, in systems possessing stationary phase in $\Delta S$ and constant local Lyapunov exponents, although the averaged fidelity has Lyapunov decay, a double-Lyapunov-exponent decay $e^{-2\lambda t}$ may appear for $t < \tau$, for the fidelity of those single initial states, for which $|k_p|$ happens to increase exponentially as $e^{\lambda t}$ [see Eq. (14)].

In order to check the above predictions, we consider the sawtooth map ($\eta = 0$) which has a constant local Lyapunov exponent, $\lambda = \ln((2+K+[(2+K)^2-4]^{1/2})/2)$. We consider here the following perturbed map

$$p_{n+1} = p_n + K(r_n - \pi) + \epsilon i \tilde{n}_i (r_n - \pi)^{i-1}, \quad i = 2, 3, 4,$$

with $N_2 = 1/2$ and $N_3 = \sqrt{14}/3\pi$. These two values $N_i$ give the same decay rate in the Fermi-golden-rule regime. However, while for $i = 2$ stationary phase of $\Delta S$ exists, in the case $i = 3$ there is no stationary phase in $\Delta S$ vs $p_0$. In the latter case, as shown in Fig. 4 (left panel) shows instead that a double-Lyapunov-exponent decay may appear for the fidelity of some particular single initial state, while the average fidelity has the Lyapunov decay (right panel).

In summary, we have derived general semiclassical expressions for the fidelity decay, at strong perturbations, which reproduce, as two particular limiting cases, previous results leading to the Lyapunov decay and to the $e^{-\lambda t}$ decay. In particular we have discussed the relevance of fluctuations in the finite-time Lyapunov exponent and we have shown that fidelity decay depends on the strength of such fluctuations in the Lyapunov regime.
