ABSTRACT

At a density near a few \( \times 10^7 \) g cm\(^{-3} \), the subsonic burning in a Type Ia supernova (SN) enters the distributed regime (high Karlovitz number). In this regime, turbulence disrupts the internal structure of the flame, and so the idea of laminar burning propagated by conduction is no longer valid. The nature of the burning in this distributed regime depends on the turbulent Damköhler number (\( Da_T \)), which steadily declines from much greater than one to less than one as the density decreases to a few \( \times 10^6 \) g cm\(^{-3} \). Classical scaling arguments predict that the turbulent flame speed \( s_T \), normalized by the turbulent intensity \( \tilde{u} \), follows \( s_T / \tilde{u} = Da_T^{1/2} \) for \( Da_T \lesssim 1 \). The flame in this regime is a single turbulently broadened structure that moves at a steady speed, and has a width larger than the integral scale of the turbulence. The scaling is predicted to break down at \( Da_T \approx 1 \), and the flame burns as a turbulently broadened effective unity Lewis number flame. This flame burns locally with speed \( s_L \) and width \( l_L \), and we refer to this kind of flame as a \( \lambda \)-flame. The burning becomes a collection of \( \lambda \)-flames spread over a region approximately the size of the integral scale. While the total burning rate continues to have a well-defined average, \( s_T \sim \tilde{u} \), the burning is unsteady. We present a theoretical framework, supported by both one-dimensional and three-dimensional numerical simulations, for the burning in these two regimes. Our results indicate that the average value of \( s_T \) can actually be roughly twice \( \tilde{u} \) for \( Da_T \gtrsim 1 \), and that localized excursions to as much as 5 times \( \tilde{u} \) can occur. We also explore the properties of the individual flames, which could be sites for a transition to detonation when \( Da_T \sim 1 \). The \( \lambda \)-flame speed and width can be predicted based on the turbulence in the star (specifically the energy dissipation rate \( \varepsilon^* \)) and the turbulent nuclear burning timescale of the fuel \( \tau_{nuc} \). We propose a practical method for measuring \( s_L \) and \( l_L \) based on the scaling relations and small-scale computationally inexpensive simulations. This suggests that a simple turbulent flame model can be easily constructed suitable for large-scale distributed SNe flames. These results will be useful both for characterizing the deflagration speed in larger full-star simulations, where the flame cannot be resolved, and for predicting when detonation occurs.

1. INTRODUCTION

In Aspden et al. (2008a, henceforth Paper I), three-dimensional simulations of resolved flames were performed that examined the interactions between turbulence and a carbon-burning flame in a Type Ia supernova (SN) at different densities. Because of the strong dependence of flame width and speed on density, this study can be viewed as a survey of the behavior of the flame at variable Karlovitz number,

\[ Ka = \frac{\tilde{u}^3 l_L}{s_L^2 T} \] (1)

Here \( s_L \) and \( l_L \) are the laminar flame speed and width, respectively, and \( \tilde{u} \) and \( l \) are the turbulent intensity (rms velocity) and integral length scale (defined conventionally as the integral of the longitudinal correlation function). For \( Ka \lesssim 1 \), the flame is laminar with propagation determined by a balance between conductive and burning timescales. Such laminar flames have a large Lewis number, which is to say thermal diffusion occurs much faster than carbon diffusion. This means that perturbing the flame surface into the ash leads to a focusing of heat by diffusion, enhancing the burning rate, burning away the perturbation. Similarly, perturbing the flame surface into the fuel leads to a defocusing of heat by diffusion, decreasing the burning rate. As a result, the flames are thermally diffusively stable. At small-to-moderate Karlovitz numbers (\( Ka \lesssim 1 \)), it was found that this thermodiffusively stable nature led to a balance between local enhancement of the flame and local extinction, and so the turbulent flame speed remained close to the laminar value.

However, once the Karlovitz number was sufficiently large (\( Ka \gtrsim 10 \)), turbulence was sufficiently strong that the turbulent mixing dominated thermal diffusion, and the flame became completely stirred (it resembled a turbulent mixing zone) and its width was greatly broadened. The turbulent flame width was also much greater than the integral length scale. While the local burning rate was greatly reduced, the overall flame speed was a factor of 5 or 6 times the laminar flame speed due to the enhanced volume of the burning.

A key result from Paper I was that at high Karlovitz number (\( Ka \approx 230 \)), turbulence dominates the mixing of fuel and heat while thermal diffusion plays only a minor role. Figure 1 shows a joint probability density function (JPDF) of fuel and temperature from Paper I. The solid red line shows the distribution from the flat laminar flame where thermal diffusion is the dominant mixing process, and the solid black line shows the distribution of fuel burning isobarically with no thermal or species diffusion. The agreement with the JPDF demonstrates that the turbulent flame is burning at an effective Lewis number close to unity—mixing is chiefly due to turbulence.

The simulations in Paper I were performed in small domains to ensure that the laminar flame was fully resolved—the domain size was approximately 25 times the laminar flame width. The aim of this paper is to investigate turbulent flame speeds in...
larger domains, with the aim of predicting high Karlovitz flame speeds in a full star, and specifically testing predictions made in Paper I. In this paper, we will refine these predictions by giving an in-depth theoretical description of the distributed burning regime, which are then compared with one- and three-dimensional simulations.

2. THEORETICAL DESCRIPTION OF THE DISTRIBUTED BURNING REGIME

There is diversity in the literature when naming the burning regimes for large Karlovitz number. Here, we use the term “distributed burning regime” (or “distributed reaction zone”) to refer collectively to all burning with large Karlovitz number \( (K_a \gtrsim 10) \). We also follow Woosley et al. (2009) in further subdividing this region based upon the turbulent Damköhler number, \( D_{\text{T}} \), to be defined below. Specifically, \( D_{\text{T}} < 1 \) will be referred to as the “well-stirred reactor” (see Peters 1986 or Woosley et al. 2009) and \( D_{\text{T}} > 1 \) as the “stirred-flame regime” (see Kerstein 2001 or Woosley et al. 2009).

2.1. The Well-stirred Reactor

Damköhler (1940) identified two burning regimes, which he referred to as “small-scale” and “large-scale” turbulence (see also Peters 1999, 2000). In the large-scale turbulence regime, laminar flames are dragged around by large turbulent eddies, which is an appropriate description of the burning in Type Ia SNe at high density (Woosley et al. 2009). The high Karlovitz number case from Paper I is in the “small-scale” turbulence regime, where the small-scale mixing is dominated by turbulence, rather than diffusion.

In this regime, the turbulent eddies are strong enough to disrupt the internal structure of the flame. The timescale of these eddies is faster than the timescale of the flame, so the flame is mixed before it can burn. Therefore, the burning takes place on an inductive timescale, or turbulent nuclear timescale, which is much slower than the laminar nuclear timescale. Damköhler predicted (by analogy with laminar flames) that the turbulent flame speed \( s_{\text{T}} \) and width \( l_{\text{T}} \) should depend upon the turbulent diffusion coefficient and the nuclear burning timescale,

\[
s_{\text{T}} = \sqrt{D_{\text{T}} \tau_{\text{T}}^{\text{nuc}}} \quad \text{and} \quad l_{\text{T}} = \sqrt{D_{\text{T}} \tau_{\text{T}}^{\text{nuc}}},
\]

where \( \tau_{\text{T}}^{\text{nuc}} \) is the turbulent nuclear timescale \( \tau_{\text{T}}^{\text{nuc}} = l_{\text{T}} / s_{\text{T}} \), and \( D_{\text{T}} \) is the turbulent diffusion coefficient \( D_{\text{T}} = \alpha \tilde{u} l \) (not to be confused with \( D_{\text{T}} \)), where \( \alpha \) is an order one constant. For convenience, take \( \alpha = 1 \), which can be thought of as absorbing the constant into the definition of the turbulent flame width, which is ambiguous.

Keeping the Karlovitz number fixed (so the energy dissipation rate of the turbulence \( \varepsilon^* = \tilde{u}^3 / l \) is a constant) and assuming that \( \tau_{\text{T}}^{\text{nuc}} \) is a constant (i.e., the limiting value has been achieved), then there is only one free parameter. This parameter can be written as a turbulent Damköhler number, defined as

\[
D_{\text{T}} \equiv \frac{\tau_{\text{T}}}{\tau_{\text{T}}^{\text{nuc}}} = \frac{s_{\text{T}}}{\tilde{u} l_{\text{T}}}.\]

It is straightforward to show that \( D_{\text{T}} \propto l^{2/3} \), where the constant of proportionality is \( (\varepsilon^{1/3} \tau_{\text{T}}^{\text{nuc}})^{-1} \). Therefore, the free parameter can be thought of in terms of the integral length scale. Both \( s_{\text{T}} \) and \( l_{\text{T}} \) are proportional to \( D_{\text{T}}^{1/2} \), so writing \( D_{\text{T}} = \tilde{u} l = \varepsilon^{1/3} l^{4/3} \), it follows immediately that both \( s_{\text{T}} \) and \( l_{\text{T}} \) scale with \( l^{2/3} \) (or equivalently \( D_{\text{T}} \)).

2.2. The Stirred-flame Regime

When the turbulence timescale \( \tau_{\text{T}} \) becomes comparable to the turbulent nuclear timescale \( \tau_{\text{T}}^{\text{nuc}} \), i.e., \( D_{\text{T}} \approx 1 \), the turbulence on the integral length scale can no longer mix the flame before it burns. Therefore, the flame cannot be broadened any further.

Figure 1. JPDF of fuel and temperature from case (e) in Paper I. The solid red line shows the distribution from the flat laminar flame where thermal diffusion is the dominant mixing process. The solid black line shows the distribution of fuel burning isobarically with no thermal or species diffusion.
and a limiting behavior is reached. Specifically, for $Da_T \gtrsim 1$, the flame burns like a unity Lewis number flame (on the scale of the flame width) with local flame speed $s_\lambda$ and width $l_\lambda$. We refer to this kind of burning as a $\lambda$-flame.

Defining a turbulent Karlovitz number as

$$Ka_T = \sqrt{\frac{\bar{u}^3 l_T}{s^3 I}}, \quad (4)$$

it can be shown that $Da_T^2 Ka_T^2 = \alpha \equiv 1$. Therefore, when the scaling relations break down at $Da_T \approx 1$, it follows immediately that the turbulent flame speed is equal to the turbulent intensity and the turbulent flame width is equal to the integral length scale.

It is the limit $Da_T \approx 1$ that divides the distributed regime into the well-stirred reactor regime and the stirred-flame regime. In particular, note that it is the turbulent Damköhler number that is the divide, and that $Da_T = \sigma Da_L$, where $\sigma = \tau_{\text{nuc}}/\tau_{\text{mec}}$ is the ratio of the nuclear timescales. Therefore, a $\lambda$-flame can only exist in the stirred-flame regime, i.e., $Da_T > 1$ and $Ka_T \gtrsim 10$.

Figure 2 shows a regime diagram, based on Peters (1999, 2000), where we emphasize the divide in the distributed burning regime. The diamonds denote the simulations from Paper I, and the squares denote the simulations from the present paper. The circle denotes the intersect of the $Ka = 230$ line with $Da_T = 1$, which denotes the $\lambda$-point, where the turbulent intensity and integral length scale are equal to the turbulent flame speed ($s_\lambda$) and width ($l_\lambda$), respectively.

We emphasize that the $\lambda$-flame speed and width are local measures, i.e., the flame burns at $s_\lambda$ on a scale of $l_\lambda$. These quantities will also vary due to turbulent intermittency. The $\lambda$-flame will respond to the local turbulence, specifically $\varepsilon$ on the scale of $l_\lambda$. Note that due to this response, the turbulent Gibson scale $l_G^T = s_\lambda^3/(\bar{u}^3/l_T)$ is equal to the $\lambda$-flame width, $l_G^T = l_\lambda$, and the Karlovitz number based on the $\lambda$-flame is always 1, i.e., $Ka_T^2 \equiv (\bar{u}/l_\lambda)/(s_\lambda^3 l_T) \equiv 1$.

The overall turbulent flame speed will be greater than $s_\lambda$ due to enhanced flame surface area and will resemble Damköhler’s large-scale turbulence regime, due to the presence of multiple $\lambda$-flames across an integral length scale. Following Peters (1999), for example, the following simple expression, based on an enhanced flame surface area, can be used to illustrate the scaling behavior in this regime,

$$\frac{s_T}{s_\lambda} = 1 + \frac{\bar{u}}{s_\lambda}, \quad (5)$$

Specifically, in the limit of high Damköhler number, the turbulent burning speed tends to the turbulent intensity, i.e., $s_T \rightarrow \bar{u}$ as $Da_T \rightarrow \infty$.

In the next section, we present calculations to investigate the turbulent flame speed as a function of Damköhler number for a high Karlovitz number flame. Specifically, we are looking for a relation of the form

$$\frac{s_T}{\bar{u}} = \varphi(Da_T), \quad (6)$$

for some dimensionless function $\varphi$. Three burning regimes are to be expected. First, for $Da_T \lesssim 1$, the turbulent flame speed and width are predicted to scale with

$$\frac{s_T}{\bar{u}} = Da_T^{1/2} \quad \text{and} \quad \frac{l_T}{l} = Da_T^{-1/2}. \quad (7)$$

Second, for $Da_T \approx 1$, the flame is predicted to reach a limiting behavior with speed $s_\lambda$ and width $l_\lambda$ (on the scale of $l_\lambda$). Finally, for $Da_T \gg 1$, the flame is predicted to burn as a $\lambda$-flame, where the overall flame speed is expected to be a few times the turbulent intensity, trending toward it as $Da_T$ tends to infinity.
2.3. The Turbulent Nuclear Timescale

Previous work has implicitly assumed that the turbulent nuclear timescale remains unaffected by the turbulence, again see Peters (1999) or Peters (2000). This was the case in Röpke & Hillebrandt (2005), where the relation

$$\frac{s_T}{s_L} \approx \left( \frac{D_T}{D_L} \right)^{1/2} \sim \left( \frac{\bar{u}l}{s_L l_L} \right)^{1/2}$$  \hspace{1cm} (8)$$

was used to derive a turbulent flame speed for a level-set method. However, as discussed in Paper I, due to the different distributions of carbon and temperature, the nuclear timescale is around an order of magnitude longer in the turbulent case. Allowing for different nuclear timescales, Equation (8) becomes

$$\frac{s_T}{s_L} = \left( \frac{\bar{u}l}{s_L l_L} \right)^{1/2} \left( \frac{\tau_{T,L}}{\tau_{T,nuc}} \right)^{1/2}.$$  \hspace{1cm} (9)$$

In Paper I, the turbulent nuclear timescale was estimated using $l_T/s_T$, based on an estimate of the turbulent flame width. It was shown that this reduces the estimate for the turbulent flame speed in Equation (9) by a factor of approximately $\alpha^{1/2} \approx 0.3$. A more refined approach for estimating $\tau_{T,nuc}$ is given below.

A corollary to the relation $D_T^2 Ka_T^2 = 1$ is that the turbulent nuclear timescale can be derived from a single measurement in the well-stirred reactor regime, specifically, the turbulent flame speed and properties of the turbulence alone. In particular, if we consider a reference case that is easily computed (e.g., case (e) from Paper I), where the turbulent intensity is $u_0$ and integral length scale is $l_0$, then only the turbulent flame speed needs to be measured. Assuming that the limiting nuclear timescale has been achieved, then the relation $D_T^2 Ka_T^2 = 1$ means that the turbulent flame width is $l_T^0 = u_0 l_0 / s_T^0$, and the turbulent nuclear timescale is $\tau_{T,nuc}^{l_T} = l_T^0 / s_T^0 = u_0 l_0 / s_T^0$. For case (e) in Paper I, this gives $l_T \approx 190 \text{ cm}$, $\tau_{T,nuc} \approx 0.0098$ s, and $\alpha \approx 0.067$ (which gives $\alpha^{1/2} \approx 0.26$).

3. SIMULATION DESCRIPTION

3.1. Three-dimensional Simulations

As in Paper I, we use a low Mach number hydrodynamics code, adapted to the study of thermonuclear flames, as described in Bell et al. (2004). The advantage of this method is that sound waves are filtered out analytically, so the time step is set by the bulk fluid velocity and not the sound speed. This is an enormous efficiency gain for low speed flames. The input physics used in the present simulations is largely unchanged, with the exception of the addition of Coulomb screening, taken from the Kepler code (Weaver et al. 1978), to the $^{12}$C$(^{12}$C,$\gamma)^{24}$Mg reaction rate. This yields a small enhancement to the flame speed and is included for completeness. The conductivities are those reported in Timmes (2000), and the equation of state (EOS) is the Helmholtz free-energy based general stellar EOS described in Timmes & Swesty (2000). We note that we do not utilize the Coulomb corrections to the electron gas in the general EOS, as these are expected to be minor at the conditions considered.

The basic discretization combines a symmetric operator-split treatment of chemistry and transport with a density-weighted approximate projection method. The projection method incorporates the equation of state by imposing a constraint on the velocity divergence. The resulting integration of the advective terms proceeds on the timescale of the relatively slow advective transport. Faster diffusion and chemistry processes are treated time implicitly. This integration scheme is embedded in a parallel adaptive mesh refinement algorithm framework based on a hierarchical system of rectangular grid patches. The complete integration algorithm is second-order accurate in space and time, and discretely conserves species mass and enthalpy. The details of the adaptive incompressible flow solver can be found in Almgren et al. (1998), the reacting flow solver in Day & Bell (2000), extension to generalized equation of state in Bell et al. (2004), and an application to the Rayleigh–Taylor instability in type Ia SNe in Zingale et al. (2005).

The non-oscillatory finite-volume scheme employed here permits the use of implicit large eddy simulation (ILES). This technique captures the inviscid cascade of kinetic energy through the inertial range, while the numerical error acts in a way that emulates the dissipative physical effects on the dynamics at the grid scale, without the expense of resolving the entire dissipation subrange. An overview of the technique can be found in Grinstein et al. (2007). Aspden et al. (2008) presented a detailed study of the technique using the present numerical scheme, including a characterization that allowed for an effective viscosity to be derived. Thermal diffusion plays a significant role in the flame dynamics, and so is explicitly included in the model, whereas species diffusion is significantly smaller, and so is not explicitly included.

The turbulent velocity field was maintained using the forcing term used in Paper I and Aspden et al. (2008). Specifically, a forcing term was included in the momentum equations consisting of a superposition of long wavelength Fourier modes with random amplitudes and phases. The forcing term is scaled by density so that the forcing is somewhat reduced in the ash. This approach provides a way to embed the flame in a zero-mean turbulent background, mimicking the much larger inertial range that these flames would experience in a type Ia SN, without the need to resolve the large-scale convective motions that drive the turbulent energy cascade. The effects of resolution were examined in detail in Aspden et al. (2008), where it was demonstrated that the effective Kolmogorov length scale is approximately 0.28$\Delta x$, and the integral length scale is approximately a tenth of the domain width. This is particularly relevant to the present study, because turbulence is the dominant mixing process. This means that the ILES approach can be used to capture the effects of turbulent mixing, which occurs on length scales much larger than the actual Kolmogorov length scale in the star.

Figure 3 shows the simulation setup. The simulations were initialized with carbon fuel in the lower part of the domain and magnesium ash in the upper, resulting in a downward propagating flame. A high-aspect ratio domain was used to allow the flame sufficient space to propagate. Periodic boundary conditions were prescribed laterally, along with a free-slip base, and outflow at the upper boundary.

3.2. One-dimensional Simulations Using the Linear Eddy Model

Simulations were also run using the linear eddy model (LEM) of Kerstein (1991). This approach simulates the evolution of scalar properties in a one-dimensional domain, which can be interpreted as a line of sight through a three-dimensional turbulent flow. Diffusive transport and chemical reactions are coupled in a model that represents the effects of real three-dimensional eddies through a so-called triplet map. The advantage of LEM is that much finer resolution and larger length scales can be
explored inexpensively. This is particularly important for the present problem, where the range of length scales is very large and the degree of turbulence very high. LEM has been successully applied to a large range of phenomena, especially turbulent terrestrial combustion. Its disadvantage is that when applied to a novel environment like a SN, there are two overall normalizatıon factors that must be adjusted, the effective turbulent dissipation rate and the integral scale. By using LEM for the present problem, we hopes to satisfy two goals—first, to show that very similar flame behavior is obtained using quite different dissipation rates and the integral scale. By using LEM for the primary diagnostic. Agreement in the turbulent flame speed provides confidence in capturing the effects of turbulent mixing (relying on the LES approach) with the new cell width; it is the turbulent flame speed that is of primary interest. A higher Damköhler number was then achieved by running in a domain 8 times larger with the new cell width, i.e., with a domain size of $1.2 \times 10^3$ cm. The turbulent intensity was adjusted accordingly to keep $\varepsilon = \bar{u}^2/l$ constant (i.e., an eight-fold increase in length scale corresponds to a two-fold increase in velocity). The whole process was then repeated several times to reach a domain size of $6.14 \times 10^3$ cm, and span a range of Damköhler numbers from the base case of $Da_T \approx 0.0064$ to $Da_T \approx 1.68$, corresponding to cases (a) through (e).

For larger length scales, the above argument no longer applies because the diffusion coefficient responsible for mixing fuel and temperature is approximately $s_j l$, and does not scale with $\bar{u} l$ for $Da_T \gtrsim 1$; even case (e) is questionably resolved. However, we have included simulations (f) and (g) at Damköhler numbers 6.6 and 26, respectively, as an indication of what we can expect for $Da_T \gtrsim 1$. The simulation properties are summarized in Table 1.

Figure 4 shows slices of density (top) and fuel consumption rate (bottom) for the seven cases (a)–(g) left-to-right. Note that the domain size increases by a factor of 8 each time. All of the figures have been normalized by the same values. Case (a) presents an extremely broad mixing region (much broader than the integral length scale), and the burning can be seen to occur at the high temperature (low density) end of the mixing zone. As the Damköhler number is increased, the relative width of the flame brush decreases as expected. Although the width of the flame brush appears to decrease, it actually increases, just more slowly than the domain size. For $Da_T \gtrsim 1$, there appears to be a sharp interface between the fuel and products. This is because of the underresolved nature of the flames—the actual flame will be a broad mixing zone, but is not fully captured here.

Figure 5 shows the turbulent flame speed evolution for the seven cases. The flame speed is evaluated by finding the rate of change of the total fuel mass in the domain divided by the product of the cross-sectional area of the domain and the fuel density,

$$s_T = \frac{1}{A(\rho X_C) \frac{d}{dV} \int_V \rho X_C dV}.$$  

The timescale has been normalized by the eddy turnover time $\tau_T = l/\bar{u}$. The solid lines denote the simulations at the full resolution ($256^3$ cells in cross-section), and the dashed lines denote the simulations at the low resolution ($32^3$ cells in cross-section). In most cases, the low-resolution simulations are in good agreement with the high-resolution simulations (the

Figure 3. Diagram of the simulation setup (shown in two dimensions for clarity). The domain is initialized with a turbulent flow and a flame is introduced into the domain, oriented so that the flame propagates toward the lower boundary. The turbulence is maintained by adding a forcing term to the momentum equations. The top and bottom boundaries are outflow and solid wall boundaries, respectively. The side boundaries are periodic.

4. RESULTS

4.1. Three-dimensional Results

The high Karlovitz case from Paper I was used as the starting point for the present study, and is referred to here as case (a). Because turbulent diffusion dominates the mixing of fuel and temperature, the resolution requirements are significantly relaxed—thermal diffusion has to be resolved to capture the laminar flame correctly, but the turbulent diffusion coefficient is much larger, and so fewer cells are required to resolve it. In fact, keeping $\varepsilon^*$ constant means that the diffusion coefficient scales as $D_T \sim l^{4/3}$, and a mixing length can be defined analogous to the Kolmogorov length scale $\eta_D = (D_T^2/\varepsilon^*)^{1/4}$, which scales as $\eta_D \sim l$. Thus, the smallest scales that need to be resolved become larger as the domain size grows.

The approach taken to achieve larger Damköhler numbers (i.e., larger length scales) was to start with case (a), which has a domain width of $1.5 \times 10^2$ cm, and run the same case at an eighth of the resolution, i.e., with a low-resolution cell width of $\Delta x_{LR} = \Delta x_{HR}/8$. The turbulent flame speed was used as the primary diagnostic. Agreement in the turbulent flame speed provides confidence in capturing the effects of turbulent mixing (relying on the LES approach) with the new cell width; it is the turbulent flame speed that is of primary interest. A higher Damköhler number was then achieved by running in a domain 8 times larger with the new cell width, i.e., with a domain size of $1.2 \times 10^3$ cm. The turbulent intensity was adjusted accordingly to keep $\varepsilon = \bar{u}^2/l$ constant (i.e., an eight-fold increase in length scale corresponds to a two-fold increase in velocity). The whole process was then repeated several times to reach a domain size of $6.14 \times 10^3$ cm, and span a range of Damköhler numbers from the base case of $Da_T \approx 0.0064$ to $Da_T \approx 1.68$, corresponding to cases (a) through (e).

For larger length scales, the above argument no longer applies because the diffusion coefficient responsible for mixing fuel and temperature is approximately $s_j l$, and does not scale with $\bar{u} l$ for $Da_T \gtrsim 1$; even case (e) is questionably resolved. However, we have included simulations (f) and (g) at Damköhler numbers 6.6 and 26, respectively, as an indication of what we can expect for $Da_T \gtrsim 1$. The simulation properties are summarized in Table 1.

Figure 4 shows slices of density (top) and fuel consumption rate (bottom) for the seven cases (a)–(g) left-to-right. Note that the domain size increases by a factor of 8 each time. All of the figures have been normalized by the same values. Case (a) presents an extremely broad mixing region (much broader than the integral length scale), and the burning can be seen to occur at the high temperature (low density) end of the mixing zone. As the Damköhler number is increased, the relative width of the flame brush decreases as expected. Although the width of the flame brush appears to decrease, it actually increases, just more slowly than the domain size. For $Da_T \gtrsim 1$, there appears to be a sharp interface between the fuel and products. This is because of the underresolved nature of the flames—the actual flame will be a broad mixing zone, but is not fully captured here.

Figure 5 shows the turbulent flame speed evolution for the seven cases. The flame speed is evaluated by finding the rate of change of the total fuel mass in the domain divided by the product of the cross-sectional area of the domain and the fuel density, $s_T = \frac{1}{A(\rho X_C) \frac{d}{dV} \int_V \rho X_C dV}$. The timescale has been normalized by the eddy turnover time $\tau_T = l/\bar{u}$. The solid lines denote the simulations at the full resolution ($256^3$ cells in cross-section), and the dashed lines denote the simulations at the low resolution ($32^3$ cells in cross-section). In most cases, the low-resolution simulations are in good agreement with the high-resolution simulations (the
Figure 4. Two-dimensional slices showing density (top) and fuel consumption rate (bottom) for all cases (a)–(g) (left-to-right). All of the figures have been normalized by the same values. It is important to note the domain increases by a factor of 8 each time. In particular, the domain size in the final case is over 250,000 times larger than the first case; despite the burning rate looking reduced, it is actually greatly increased.

only real outlier is case (d) where the low-resolution simulation over-predicts the flame speed by 48%). Table 2 shows the mean flame speeds at both resolutions in each case.

Figure 6 shows the turbulent burning speeds normalized by the turbulent intensity as a function of Damköhler number. Case (a) is the low Damköhler number on the left, increasing to the right to case (g). The marker denotes the mean in each case, and the vertical line denotes the range of values obtained during the averaging period (note that it is not the standard deviation). The solid line is the expected scaling relation from Equation (7). The dashed lines denote $Da_T = 1$ and $s_T = \tilde{u}$, where the scaling relation is predicted to break down. Cases (a)–(e) are in very good agreement with the predicted scaling. We note that for cases (d) and (e), the flame speed measured is enhanced by the area of the flame that is burning, which can be increased by turbulence here because the flame brush is now smaller than
Figure 5. Turbulent flame speeds $s_T$ as a function of time (normalized by turbulent timescale $\tau_T$). The solid lines denote the simulations at the full resolution ($256^2$ cells in cross section), and the dashed lines denote the simulations at the low resolution ($32^2$ cells in cross section).

Table 2

| Case                | High resolution (cm s$^{-1}$) | Low resolution (cm s$^{-1}$) | Percentage error |
|---------------------|-------------------------------|-------------------------------|------------------|
| (a)                 | $1.84 \times 10^6$            | $1.86 \times 10^6$            | 1.1              |
| (b)                 | $8.10 \times 10^4$            | $8.57 \times 10^4$            | 5.8              |
| (c)                 | $3.51 \times 10^5$            | $3.91 \times 10^5$            | 11.4             |
| (d)                 | $1.56 \times 10^6$            | $2.31 \times 10^6$            | 48.1             |
| (e)                 | $5.94 \times 10^6$            | $6.5 \times 10^6$             | 9.4              |

| (g)                 | $3.49 \times 10^7$            | $3.16 \times 10^7$            | $-9.5$           |

4.2. One-dimensional Results

LEM was used to simulate the same conditions as in Table 1 except that in each case the integral scale was multiplied by three and finer resolution was employed (Table 3). Roughly 40,000 time points were sampled for each case. The average flame speeds are plotted in Figure 6. For $Da_T \lesssim 1$, the agreement with the three-dimensional simulations is excellent. Both show the same scaling relation as well as agreeing on the actual value of the speed. However, at large values of $Da_T$, the LEM results are almost a factor of 2 smaller. There could be several reasons for this. First, there are fundamental differences in the two approaches. LEM does not capture all of the multi-dimensional effects and has not been calibrated for this regime. Second, the resolution of the three-dimensional study is low and not all burning structures are well resolved. Studies with LEM suggest a mild dependence of $s_T$ on the resolution with slower speeds at higher resolution.

4.3. Variability of the Turbulent Flame Speed

Figure 8 compares the PDFs of the normalized local burning rate in the three-dimensional and LEM calculations. To compare the three-dimensional results as closely as possible with LEM, the PDFs were evaluated by integrating the fuel consumption along line-outs, i.e. over individual columns of data as a function of height. Each PDF was then normalized by the mean burning speed. The PDFs have been shifted along the $y$-axis for clarity.

In case (a), the PDF has a narrow Gaussian distribution centered around the mean flame speed. As the Damköhler number increases, the PDF becomes broader, i.e. a greater range of burning rates is observed locally.
and location is smooth and the burning time well defined. There is only one flame structure. Consequently the speed does not vary greatly from the average.

In the stirred flame, however, there are multiple regions of burning. Sometimes the burning is very fast, especially when a large single eddy envelops a new region of fuel. At other times, it almost goes out. The PDF thus shows a large spread in speed. Occasionally, the overall burning proceeds at a rate that is 2.5–3 times the average. Since the average itself is roughly twice $\bar{u}$, this implies an overall burning rate up to 6 times $\bar{u}$.

Table 3

| Case          | (a)       | (b)       | (c)       | (d)       | (e)       | (f)       | (g)       |
|---------------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|
| Turbulent intensity, $\bar{u}$ (cm s$^{-1}$) | $2.47 \times 10^5$ | $4.93 \times 10^5$ | $9.86 \times 10^5$ | $1.97 \times 10^6$ | $3.95 \times 10^6$ | $7.89 \times 10^6$ | $1.58 \times 10^7$ |
| Integral length scale, $l$ (cm)       | $4.50 \times 10^1$ | $3.60 \times 10^2$ | $2.88 \times 10^3$ | $2.30 \times 10^4$ | $1.84 \times 10^5$ | $1.48 \times 10^6$ | $1.18 \times 10^7$ |
| Resolution, $\Delta x$ (cm)           | $4.89 \times 10^{-1}$ | $2.93 \times 10^0$ | $1.47 \times 10^1$ | $9.77 \times 10^1$ | $7.32 \times 10^2$ | $2.44 \times 10^3$ | $2.44 \times 10^4$ |
| Average speed (cm s$^{-1}$)            | $1.96 \times 10^4$ | $7.26 \times 10^4$ | $2.50 \times 10^5$ | $8.70 \times 10^5$ | $2.85 \times 10^6$ | $8.36 \times 10^6$ | $2.14 \times 10^7$ |

Figure 6. Turbulent flame speeds normalized by turbulent intensity $s_T/\bar{u}$ as a function of turbulent Damköhler number $Da_T$. The solid black line denotes the expected scaling behavior for $Da_T \lesssim 1$, bounded by the dashed lines. The flame speeds appear to be in good agreement with the predicted scaling, and despite the lack of resolution, appear to roll over when $Da_T \gtrsim 1$. The crosses denote the mean speeds from the LEM calculations.

Figure 7. Volumetric rate of fuel consumption. The solid line is the measured rate $As_T$, where $A$ is the cross-sectional area, the dotted line is the product of the limiting flame speed $s_\lambda$ with the measured flame surface area, and the dash-dotted line is the latter adjusted by a factor of 0.67 for case (f) and 2.16 for case (g). There is a definite correlation between the flame surface area and the fuel consumption, but the estimate $s_\lambda$ appears to be an overprediction for case (f) and an underprediction for case (g). We speculate that this is due to the underresolved nature of these cases and that $s_\lambda$ is still a reasonable estimate for a turbulent flame model.
5. CONCLUSIONS

New one- and three-dimensional simulations have been presented to clarify and quantify the nature of carbon burning in a Type Ia SN in the distributed burning regime. The characteristics of distributed burning depend upon the Damköhler number, and a range of $Da_T$ from 0.006 to 26 has been explored. For $Da_T \lesssim 1$, the expected scaling relations were demonstrated,

$$\frac{s_T}{u} = Da_T^{1/2} \quad \text{and} \quad \frac{l_T}{l} = Da_T^{-1/2}. \quad (11)$$

For $Da_T \gtrsim 1$, these relations break down and the turbulent flame reaches a maximum local flame speed $s_\lambda$ and width $l_\lambda$, measured on the scale of $l_\lambda$. This $\lambda$-flame interacts with turbulent eddies with length scales between $l_\lambda$ and the integral length scale $l$, which enhances the flame surface area. The average turbulent flame properties are constrained by the large scales (see also Woosley et al. 2009). This leads to an average overall turbulent flame speed, which to factor-of-2 accuracy is given by the turbulent intensity, $\bar{u}$. For the range of $Da_T \gtrsim 1$ studied here, a good approximation is $s_T = 2\bar{u}$.

5.1. Consequences for Large-scale Simulations

Large-scale simulations (i.e., of a full star) will require a turbulent flame model. One of the consequences of the results presented here is that the $\lambda$-flame is ideally suited to the level-set approach, as it burns locally with speed $s_\lambda$ and width $l_\lambda$, measured on the scale of $l_\lambda$. This $\lambda$-flame interacts with turbulent eddies with length scales between $l_\lambda$ and the integral length scale $l$, which enhances the flame surface area. The average turbulent flame properties are constrained by the large scales (see also Woosley et al. 2009). This leads to an average overall turbulent flame speed, which to factor-of-2 accuracy is given by the turbulent intensity, $\bar{u}$. For the range of $Da_T \gtrsim 1$ studied here, a good approximation is $s_T = 2\bar{u}$.

For $Da_T \gtrsim 1$, these relations break down and the turbulent flame reaches a maximum local flame speed $s_\lambda$ and width $l_\lambda$, measured on the scale of $l_\lambda$. This $\lambda$-flame interacts with turbulent eddies with length scales between $l_\lambda$ and the integral length scale $l$, which enhances the flame surface area. The average turbulent flame properties are constrained by the large scales (see also Woosley et al. 2009). This leads to an average overall turbulent flame speed, which to factor-of-2 accuracy is given by the turbulent intensity, $\bar{u}$. For the range of $Da_T \gtrsim 1$ studied here, a good approximation is $s_T = 2\bar{u}$.

5.2. Consequences for Detonation

The instantaneous flame speed for $Da_T \gtrsim 1$ is irregular, with frequent excursions up to 2.5 times the average, which is approximately twice the turbulent intensity for the simulations presented here. These variations could be crucial if a transition to detonation is to occur. Detonation will not happen in the laminar regime, i.e., at high density, because each flamelet burns at a steady rate and has a thickness that is far below the critical mass for detonation. It is also unlikely to happen in the well-stirred reactor regime, because the burning is steady and slower than the turbulence on the integral scale, which in turn is subsonic. The burning timescale is very long in the well-stirred regime, making it very difficult to burn, for example, a 10 km region on a sound crossing time.

Thus if detonation is to occur spontaneously, it is likely to happen in the stirred-flame regime. Even there though, $Da_T$ should not be too large, or the mixed regions will not
burn supersonically (recall $s_T \to \tilde{u}$ for large $Da_T$). The best conditions therefore occur where there are multiple $\lambda$-flames across an integral length scale, i.e., for small $Da_T \gtrsim 1$ (Woosley 2007; Woosley et al. 2009). The calibration of LEM determined by comparison with the three-dimensional studies suggests a normalization constant of $C = 5$ is most appropriate for $Da > 1$ and this is the value used by Woosley et al. (2009). This strengthens their conclusion that a detonation is possible if $\tilde{u}$ exceeds about one-fifth sonic.
