(Dated: August 5, 2004)

In the present work we investigate the adequacy of broken-symmetry unrestricted density functional theory (DFT) for constructing the potential energy curve of nickel dimer and nickel hydride, as a model for larger bare and hydrogenated nickel cluster calculations. We use three hybrid functionals: the popular B3LYP, Becke’s newest optimized functional Becke98, and the simple FSLYP functional (50% Hartree-Fock and 50% Slater exchange and LYP gradient-corrected correlation functional) with two basis sets: all-electron (AE) Wachters+f basis set and Stuttgart RSC effective core potential (ECP) and basis set. We find that, overall, the best agreement with experiment, comparable to that of the high-level CASPT2, is obtained with B3LYP/AE, closely followed by Becke98/AE and Becke98/ECP, FSLYP/AE and B3LYP/ECP give slightly worse agreement with experiment, and FSLYP/ECP is the only method among the ones we studied that gives an unacceptably large error, underestimating the dissociation energy of Ni$_2$ by 28%, and being in the largest disagreement with the experiment and the other theoretical predictions. We also find that for Ni$_2$, the spin-projection for the broken-symmetry unrestricted singlet states changes the ordering of the states, but the splittings are less than 10 meV. All our calculations predict a $\delta$-hole ground state for Ni$_2$ and $\delta$-hole ground state for NiH. Upon spin-projection of the singlet state of Ni$_2$, almost all of our calculations: Becke98 and FSLYP both AE and ECP and B3LYP/AE predict $^2(d_{\sigma}^A d_{\sigma}^B)$ or $^1(d_{\sigma}^A d_{\sigma}^B)$ ground state, which is a mixture of $^1\Sigma^+_u$ and $^3\Gamma_u$. B3LYP/ECP predicts a $^3(d_{\sigma}^A d_{\sigma}^B)$ (mixture of $^3\Sigma^+_u$ and $^3\Gamma_u$) ground state virtually degenerate with the $^1(d_{\sigma}^A d_{\sigma}^B)$ state. The doublet $\delta$-hole ground state of NiH predicted by all our calculations is in agreement with the experimentally predicted $^2\Delta$ ground state. For Ni$_2$, all our results are consistent with the experimentally predicted ground state of $^0_g$ (a mixture of $^1\Sigma^+_u$ and $^3\Sigma^-_g$) or $^0_u$ (a mixture of $^3\Sigma^+_u$ and $^3\Sigma^-_u$).

I. INTRODUCTION

During the last decades clusters have been extensively studied because of their potential applications, their theoretical value in understanding the transition from isolated atomic systems to condensed matter and their relevance to the study of surface processes and heterogeneous catalysis. The rapid development of experimental techniques in recent years has made it possible both to obtain size-controlled transition metal clusters and to study their reactivity against chemisorption processes.

Methods for studying properties and behavior of clusters have been developed, and a review on computational studies of clusters has been written by Freeman and Doll. There have been many studies on nickel clusters using various methods of exploring the potential energy surfaces (PES). The construction of such potential surfaces is a major problem, especially for transition metal clusters. Many methods have been used to construct PES’s for nickel clusters, ranging from semiempirical—Finis-Sinclair type, semi-empirical—tight binding and extended Hückel, to ab initio or mixed empirical—ab initio approaches. Recently, there have been studies of hydrogen atoms on Cu surfaces within the density functional framework. It has been found that semiempirical methods are insufficient for accurate description of such systems, and first principle quantum-mechanical methods are needed to obtain a proper description of the hydrogen binding site.

Our long-term goal is to explore the structure and dynamics of clusters, including nickel and nickel hydride systems. The combination of the physical complexity and the computational demands of these systems necessitate that the microscopic force laws that are utilized in such simulations be both efficient and reliable.

Among the correlated electronic structure methods the best candidate is clearly density functional theory (DFT) because of its ability of reaching high accuracy—similar to coupled-cluster CCSD(T) method for second-row elements when hybrid exchange-correlation functionals are used. Moreover, DFT (using hybrid function-
als) is computationally not much more expensive than Hartree-Fock.

While there have been a number of DFT calculations reported on small nickel clusters [13, 20, 21, 22, 23, 24, 25, 26], some results appear to be inconsistent both with respect to available experimental data and/or with respect to other theoretical predictions.

The works of Yanagisawa et al. [27] and Barden et al. [28] on the performance of DFT on the first transition metal series have shown that non-hybrid functionals (BLYP [24, 30], BOP [24, 32], BOP [24, 33] and PW91 [34]) and hybrid functionals (B3LYP [30, 35], BHLYP [30, 36]) give an overall similar description for 3 transition metal dimers, with the non-hybrid ones giving better bond lengths and the hybrid ones better dissociation energies. However, while Yanagisawa et al. [27] obtain good agreement with experiment for nickel dimer for the popular B3LYP [30, 35] — as model systems for nickel hydride using broken symmetry unrestricted DFT approach with hybrid functionals.

In the present work we study the nickel dimer and nickel hydride calculations (Hartree-Fock and DFT with hybrid functionals). This prompted us to use symmetry breaking in unrestricted DFT for describing the lowest singlet state of nickel dimer. With larger cluster calculations in mind, we also used broken symmetry unrestricted DFT to better describe bond breaking in all states of nickel dimer and nickel hydride.

It has been argued that broken-symmetry unrestricted calculations (Hartree-Fock and DFT with hybrid functionals) are useful for describing systems with weakly coupled electron pairs [18, 37, 38, 39, 40, 41, 42]. Ni$_2$ is definitely such a case, as previously observed by Basch et al. [13]. As argued by Cremer [18], the combination of hybrid exchange-correlation functional with symmetry breaking leads to a better description of systems in which static correlation is present than does the restricted DFT formalism. Finally, we believe that the formalism used to describe any system is solely dictated by the objective of the calculation. For a variational approach, and DFT can be regarded as such — aside from the exchange-correlation functional, — the more flexible is the form of the trial function (density), the lower is the obtained energy. Since our interest is mainly in the energetics of nickel clusters, the best choice for us seems to be the unrestricted broken symmetry DFT approach with hybrid functionals.

In the present work we study the nickel dimer and nickel hydride using broken symmetry unrestricted DFT with hybrid exchange-correlation functionals — mainly the popular B3LYP [30, 37] — as model systems for larger bare and hydrogenated nickel clusters in an attempt to establish what might comprise a minimally reliable method for more extensive nickel cluster calculations.

The outline of the reminder of the present paper is as follows: Section IV concludes with suggestions for further research based on the present findings.

II. COMPUTATIONAL DETAILS

The DFT calculations reported in this paper are carried out with NWChem [43] computational chemistry package, using the unrestricted Kohn-Sham approach, allowing for symmetry breaking, and using a finite orbital (spherical Gaussian) basis set expansion and charge density fitting.

Hartree-Fock (HF) and second order Møller-Plesset (MP2) calculations are performed for comparison for the states of the Ni atom and are done in unrestricted form.

Throughout the paper we will use the notation $M(h^Ah^B)$ for the states of nickel dimer, where $M$ is the multiplicity, $h^A$ and $h^B$ are the unoccupied (hole) orbitals in the 3$d$ shell on the two Ni atoms, denoted $A$ and $B$. The broken symmetry singlet states (with $S_z = 0$ and $\langle S^2 \rangle = 1$) are denoted by $1^S(h^Ah^B)$.

In general, an unrestricted Slater or Kohn-Sham determinant is not an eigenfunction of the total spin operator $S^2$, and the results can only be characterized by the number of $\alpha$ and $\beta$ electrons. However, following common usage, we refer to the states that differ in the number of $\alpha$ and $\beta$ electrons by 0 as singlets, by 1 as doublets, and so on. We explicitly identify pure spin states where relevant.

A. Exchange-Correlation Functionals

We used three hybrid exchange-correlation functionals: the very popular B3LYP — composed of the B, Becke’s three-parameter hybrid exchange functional [35] and LYP [30] correlation functional — is the first choice because it is well known and extensively characterized. Becke’s newest optimized functional, Becke98 [44] is also used, since it is supposed to be, in a certain sense, the best obtainable exchange-correlation functional within the gradient-corrected framework. The hybrid composed of half Slater exchange [45], half Hartree-Fock-exchange and LYP [30] correlation, named here FSLYP is also used for comparison, as it is the simplest theoretically-justifiable hybrid method and is reported to perform rather well [10, 11].

B. Basis sets

All calculations are performed with spherical basis sets. As all-electron (AE) basis sets, Wachters+f basis set [16, 17, 18, 19], a [14s11p6d3f]/(8s6p4d1f) contraction is used for nickel and 6-311++G(2d,2p), a [6s2p]/(4s2p) contraction for hydrogen.
Effective-core potentials (ECP) are also explored, since they greatly reduce computational cost. Stuttgart RSC ECP effective core potentials basis set 50, 51 are used for nickel, as they provide a similar quality of valence basis functions as Wachters+f.

Ahlrichs Coulomb Fitting 52, 53 basis is used as a charge density (CD) fitting basis only for the all-electron calculations, as it significantly reduces computing time, especially for larger systems. When not specified otherwise, all reported all-electron results are obtained using charge density fitting.

We did not use charge density fitting with ECP because of the large errors that resulted when we tried the use of Ahlrichs Coulomb Fitting basis in combination with Stuttgart RSC ECP. For example, for B3LYP functional, CD fitting error is as much as 0.3 eV for both the interconfigurational energies of Ni atom and the binding energy of Ni2. Please refer to Appendix A for discussion of the accuracy of charge density fitting.

C. Numerical integration and convergence

The numerical integration necessary for the evaluation of the exchange-correlation energy implemented in NWChem uses an Euler-MacLaurin scheme for the radial components (with a modified Mura-Knowles transformation) and a Lebedev scheme for the angular components. We use three levels of accuracy for the numerical integration that are used in our DFT calculations, labeled by the corresponding keywords from NWChem (medium, fine and xfine).

The reported atomic calculations are those obtained with the xfine grid. For geometry optimization and vibrational frequency calculations we use the fine grid. And for the potential energy curve (PEC) scans we used the medium grid. The maximum number of iterations is set to 100 in all calculations.

Please refer to Appendix B for details on numerical integration and convergence criteria.

D. Initial guess

For all DFT methods we first performed a calculation for Ni atom using fractional occupation numbers (FONs) 54, as implemented in NWChem. We use an exponent of 0.01 Hartree for the Gaussian broadening function. We then use the molecular orbitals from the FONs calculation, after proper reordering, as initial guess for computing the \(^3F\) and \(^3D\) states of Ni atom. We use \(t^6\sigma_g^2\) configuration in the \(O_h\) symmetry group for the \(^3F\) state. In order to obtain the lowest energy possible for the \(^3D\) state, we scan all hole positions: \(d_{xy}, d_{x^2-y^2}\) and \(d_{yz}\) using \(D_{4h}\) symmetry group, and \(d_{xz}\) and \(d_{yz}\) using \(D_{2h}\) symmetry group, enforcing the position of the hole with a maximum overlap condition.

For Ni\(_2\) and NiH, we use a broken-symmetry initial guess of the form: \(3d^94s^1↑↑↓ + ↓↑ 3d^94s^1\) for singlet Ni\(_2\), \(3d^94s^1↑↑↓ + ↓↑ 3d^94s^1\) for triplet Ni\(_2\) and Ni\(_3d^94s^1↑↑↓ + ↓↑ 1s^3\) for NiH. As initial guess molecular orbitals we use those from the Ni atom calculations, sweeping through all unique positions of the holes in the 3d orbitals of Ni atom(s), and enforcing the position of the hole(s) with a maximum overlap condition.

E. Geometry optimization

Geometry optimizations are performed using the DRIVER module of NWChem using NWChem’s default convergence criteria (in atomic units): 4.5 \(\cdot\) \(10^{-4}\) maximum and 3.0 \(\cdot\) \(10^{-4}\) root mean square gradient, 1.8 \(\cdot\) \(10^{-3}\) maximum and 1.2 \(\cdot\) \(10^{-3}\) root mean square of the cartesian step. These convergence criteria give a maximum error in equilibrium bond length of less than \(\approx 10^{-3}\) Å for Ni\(_2\) and less than \(\approx 5\cdot10^{-4}\) Å for NiH. The available precision is set to 5 \(\cdot\) \(10^{-7}\) Hartree for the fine grid and 5 \(\cdot\) \(10^{-8}\) Hartree for the xfine grid.

F. Vibrational frequencies

Harmonic vibrational frequencies are calculated using NWChem’s VIB module with the default options. Since analytical Hessian for open shell systems is not available for the exchange-correlation functionals used, the Hessian is computed by finite differences with \(\Delta = 0.01\) Bohr, which gives an estimated error for the vibrational frequencies of \(\approx 0.5\) cm\(^{-1}\) (\(\approx 0.25\%\)) for Ni\(_2\) and \(\approx 2\) cm\(^{-1}\) (\(\approx 0.1\%\)) for NiH.

G. Spin and Symmetry Projection

In general, an open-shell Slater or Kohn-Sham determinant is not an eigenfunction of the total spin operator \(S^2\). However, spin-adapted configurations can be obtained as combinations of (a small number of) restricted determinants 55, 56. Unrestricted determinants are not eigenfunction of the total spin operator \(S^2\), either, and they cannot be spin-adapted by combining a small number of unrestricted determinants 55. However, for antiferromagnetic coupling of two weakly interacting identical high spin monomers, Noodleman 57 derived an approximate spin projection scheme that is correct to the first order in the overlap integrals. Ni\(_2\) can be well approximated by such a model.

As previously observed by Basch et al. 19, the electronic structure of nickel clusters corresponds roughly to a model in which the 3d electrons can be viewed as weakly interacting localized 3d\(^9\) units bound together primarily by 4s electrons. If the 4s electrons are paired in a \(\sigma\) bond, then Ni\(_2\) has two possible spin states: singlet and triplet. However, the open-shell singlet state can not
be represented by a single determinant, and the broken-symmetry single determinant \( \Psi_B \) obtained by putting one of the open-shell electrons in a spin \( \alpha \) \( d \) orbital on one of the Ni atoms and the other electron in a spin \( \beta \) \( d \) orbital on the other Ni atom is not pure singlet, but an equal mixture of singlet and triplet (using \( |S,S_z\rangle \) notation for the spin states):

\[
\Psi_B = \frac{1}{\sqrt{2}} |0,0\rangle + \frac{1}{\sqrt{2}} |1,0\rangle
\]

with the expectation value of the total spin \( \langle \Psi_B | S^2 | \Psi_B \rangle = 1 \). In agreement with this model, for the broken-symmetry calculations of the \( S_z = 0 \) state of the Ni dimer the expectation value of the total spin \( \langle S^2 \rangle \) is close to the exact value of 1 for the broken-symmetry mixed state, and for the triplet \( \langle S_z = 1 \rangle \) state, \( \langle S^2 \rangle \) is close to the exact value of 2 (in both cases, the relative absolute differences between the computed and the exact values are less than 2\%). Mulliken population analysis also supports the weakly interacting 3\( d \) units model. For the triplet nickel dimer there is a Mulliken spin population of 1.00 on each Ni atom, and for the broken symmetry singlet there is a Mulliken spin population of 1.1 on one of the Ni atoms and -1.1 on the other.

Using the approximate projection method of Noolde-man \[58\], the energy of the pure singlet state, \( E(0) \), can be obtained from the energy of the unrestricted broken-symmetry singlet, \( E_B \), and the energy of the triplet, \( E(1) \):

\[
E(0) = 2E_B - E(1).
\] (1)

The same result can be also obtained by the spin projection technique (see, e.g., Refs. \[57\] and \[58\]).

\( \text{Ni}_2 \) belongs to \( D_{\text{sch}} \) point symmetry group, and the irreducible representations (irreps.) are good quantum numbers for the molecular states. We combine the spin projection with symmetry projection to extract the maximum information possible from the single-determinant Kohn-Sham DFT calculations. From simple group-theoretical considerations one can find that the pure spin and symmetry states of \( \text{Ni}_2 \) that arise from \( d_\delta \) orbitals, which are found to give the lowest energy states for all calculations, are: \( 1\Sigma_u^+, 1\Gamma_g, 1\Sigma_u^- 3\Sigma_g^- 3\Sigma_u^\dag \) and \( 3\Gamma_u \). Within the model of two weakly interacting 3\( d \) units, for the purpose of projection we consider only the active electrons and the active orbitals on each center, namely \( d^3_{x^2-y^2}, d^2_{xy}, d^2_{x^2-y^2} \) and \( d^B_{xy} \).

The projection has been carried out using the projection operators technique in \( D_{\text{sch}} \), which the smallest subgroup of \( D_{\text{sch}} \) in which all irreps. arising from the \( (d^A)^1(d^B)^1 \) configuration can be completely correlated, and the following equations relating the energies of the pure spin and symmetry states listed above to the energies of the computed triplet and projected singlet states are obtained:

\[
E\left( ^1(d^A_{x^2-y^2}d^B_{x^2-y^2}) \right) = \frac{1}{2} \left[ E\left( ^1\Sigma_u^+ \right) + E\left( ^1\Gamma_g \right) \right] 
\] (2a)

\[
E\left( ^3(d^A_{x^2-y^2}d^B_{x^2-y^2}) \right) = \frac{1}{2} \left[ E\left( ^3\Sigma_u^+ \right) + E\left( ^3\Gamma_u \right) \right] 
\] (2b)

\[
E\left( ^1(d^A_{xy}d^B_{xy}) \right) = \frac{1}{2} \left[ E\left( ^1\Sigma_u^\dag \right) + E\left( ^1\Gamma_g \right) \right] 
\] (2c)

\[
E\left( ^3(d^A_{xy}d^B_{xy}) \right) = \frac{1}{2} \left[ E\left( ^3\Sigma_u^\dag \right) + E\left( ^3\Gamma_u \right) \right]. 
\] (2f)

These equations contain the maximal information that can be obtained from single-determinant calculations.

From equations \( \[2f\] \) we can derive the (partially) symmetry-adapted equivalent of Eq. \( \[1\] \):

\[
E\left( ^1(h^AH^B) \right) = 2E\left( ^1,^3(h^AH^B) \right) - E\left( ^3(h^AH^B) \right)
\] (3)

where \( (h^AH^B) \) represents each of \( (d^A_{x^2-y^2}d^B_{x^2-y^2}), \)

\( (d^A_{x^2-y^2}d^B_{xy}), \) and \( (d^A_{xy}d^B_{xy}) \) for the spin projection has to be done separately for each of the combinations of holes \( (d^A_{x^2-y^2}d^B_{x^2-y^2}) \) and \( (d^A_{x^2-y^2}d^B_{xy}) \) for consistency check.

Since the bond lengths for the pure spin states are different from each other and from the mixed state, we use a harmonic approximation of the potential around equilibrium bond length for each state:

\[
E(d) = -D_c + \frac{1}{2} \mu \omega_c^2 (d - d_c)^2
\]

and solve the resulting equations for \( d_c \) (equilibrium bond length), \( D_c \) (dissociation energy) and \( \mu \omega_c \) (vibrational frequency) for the projected state (here \( \mu \) denotes the reduced mass of the molecule).

### III. RESULTS AND DISCUSSIONS

#### A. Nickel Atom

The ground state of the nickel atom is \( ^3F_4(3d^84s^2) \) \[59\]. However, since our calculations do not include spin-orbit coupling, we use weighted averages over the \( J \) components of the experimental data for comparison, which makes \( ^3D(3d^84s^1) \) the ground state, with \( ^3F(3d^84s^2) \) state only 0.03 eV higher, and \( ^1S(3d^9) \) state 1.74 eV above the ground state.

As first estimated by Martin and Hay \[60\] and confirmed by full relativistic calculations done by Jeng and...
Hsue [62] the relativistic effects in the 3d transition metal series are important. Therefore, in comparing our non-relativistic calculations with the experiment we take such effects into account by subtracting the estimated values reported by Martin and Hay from the experimental values. After this correction (see Table I for details), the ground state remains $^3D$, with $^3F$ state 0.39 eV higher, and $^1S$ state 1.53 eV above the ground state. These values will be referred to as “relativistically corrected (RC) experimental values.”

In Table I we choose to utilize the Martin and Hay [60] relativistic corrections as opposed to the ones computed by Jeng and Hsue [62] because they include the additional $^1S(3d^{10})$ configuration. The results of the recent relativistic calculations in the RESC approximation (relativistic scheme by eliminating small components) reported by Yanagisawa et al. [24] do not lend themselves to an analysis of relativistic corrections. Moreover, these calculations seem to be at odds with the two previous calculations.

Our results, summarized in Table I, show that only the DFT/Wachters+f calculations with B3LYP and Becke98 hybrid exchange-correlation functionals predict a $^3D$ ground state, although B3LYP/ECP predicts the $^3D$ state only 0.01 eV above the $^3F$ ground state.

It is worth mentioning that, for all our DFT calculations, there are differences between the components of the $^3D$ state of Ni and these differences range from 4 meV to 37 meV. We report the energy of the $^3D$ component with the lowest energy as the energy of the $^3D$ state. It is also worth mentioning that the B3LYP/ECP calculations fail to converge for the spin $\alpha$ $d_{xy}$, $d_{yz}$, $d_{zx}$, and $d_{x^2-y^2}$-hole components of the $^3D$ state.

The all-electron calculations with B3LYP and Becke98 XC functionals also predict an ordering of the $^3D$, $^3F$ and $^1S$ states in agreement with the experiment.

The values of the computed energies of $^3F$ (relative to $^3D$) differ from the observed experimental values by 0.30 eV (B3LYP) and 0.26 eV (Becke98). However, when compared with the relativistically corrected experimental values, the differences drop to only −0.06 eV and −0.10 eV, respectively. On the other hand, the computed energies of $^1S$ (relative to $^3D$) are larger than the observed experimental values by 0.16 eV (B3LYP) and 0.04 eV (Becke98), and larger than the relativistically corrected experimental values by 0.37 eV and 0.25 eV, respectively. However, the larger errors in the $^1S$ is less important for the purpose of nickel cluster calculations.

Hartree-Fock calculations predict $^3F$ ground state, $^3D$ 1.44 eV higher and $^1S$ 5.81 eV above the ground state in agreement with numerical HF calculations of Martin and Hay [63], but with large errors compared to the RC experimental values. MP2 calculations predict $^1S$ ground state, with $^3D$ and $^3F$ states 0.27 eV and 1.41 eV higher, respectively.

The unoptimized FSLYP functional is, as expected, the least accurate. With the Wachters+f basis it yields results that differ from the RC experimental values and B3LYP and Becke98 results by $\approx −0.5$ eV for $^3F$ and by $\approx 0.5$ eV for $^1S$.

The effective core potentials (ECP) tend to overstabilize $^3F$ by 0.2 − 0.5 eV and destabilize $^1S$ by 0.2 − 0.4 eV (relative to $^3D$) with respect to the all-electron counterparts. Thus, all our DFT/ECP calculations predict $^3F$ ground state. However, the B3LYP/ECP calculations yield $^3D$ only 0.01 eV above the $^3F$ ground state, which can be considered an acceptable error for the dissociation energy of nickel dimer which is of order of 2 eV, given the savings of using ECPs.

### B. Nickel Dimer

The determination of the ground state of Ni$_2$ has been debated over the last few decades. According to the recent results [65, 66], the most plausible candidates are spin-orbit coupled states of $\Omega = 0^+ \ (\text{a mixture of } ^3\Sigma^+_g \text{ and } ^1\Sigma^+_g)$ and $\Omega = 0^- \ (\text{a mixture of } ^3\Sigma^-_u \text{ and } ^1\Sigma^-_u)$.

The bond lengths ($d_\text{c}$), dissociation energies ($D_\text{c}$) [72] and vibrational frequencies ($\omega_\text{c}$) for the ground state of Ni$_2$ from different calculations are reported in Table II along with experimental values and results from other theoretical studies. The results in Table II are listed in the order of decreasing average absolute relative deviations (AARD) from experimental values of bond length ($d_\text{c}$), dissociation energy ($D_\text{c}$) and vibrational frequency ($\omega_\text{c}$).

Please note that our calculations are non-relativistic and do not include spin-orbit coupling, and spin-orbit perturbed values of molecular properties of interest for Ni$_2$ are not available in the literature. To account for that, we have subtracted the CASPT2 relativistic corrected experimental values with relativistic corrections subtracted.

### Table I: Energies of atomic states of Ni. Values are in eV, relative to the ground state.

| State       | Exp. | RC | Exp.-RC | UHF | MP2 | FSLYP | B3LYP | Becke98 |
|-------------|------|----|---------|-----|-----|-------|-------|---------|
| $^3D(3d^94s^1)$ | 0    | 0  | 1.44    | 0.27| 0.12| 0.32  | 0.01  | 0.20    |
| $^3F(3d^94s^2)$ | 0.03 | −0.36 | 0.39 | 0   | 1.41| 0     | 0.36  | 0.29    |
| $^1S(3d^{10})$ | 1.74 | 0.21 | 1.53   | 5.81| 0   | 2.62  | 3.02  | 1.90    | 2.21  | 1.78  | 2.37  |

| a | Weighted averages over the J components of the experimental values. [62].
| b | Martin and Hay estimations of relativistic corrections from Ref. [60].
| c | Experimental values with relativistic corrections subtracted.
TABLE II: Ground state of Ni₂ – comparison between computations and experiment. The reported singlet states from our calculations are projected. $d_c$ – bond length (Å), $D_e$ – dissociation energy, relative to ground state Ni atoms (without zero-point correction, eV), $\omega_e$ – vibrational frequency (cm$^{-1}$). The relative deviations from the experimental values are given in parentheses, and the average (AARD) and maximum (MARD) absolute relative deviations from experimental values of $d_c$, $D_e$ and $\omega_e$ are listed under AARD and MARD columns, respectively.

| Method         | State                                                                 | $d_c$   | $D_e$       | $\omega_e$ | AARD  | MARD |
|----------------|-----------------------------------------------------------------------|---------|-------------|------------|-------|------|
| FSLYP/ECP      | $1(d_{x^2-y^2}^{A}d_{z^2}^{B})$                                       | 2.236   | (1.5)       | 1.325      | (28.4) | 283.0| (14.9) | 14.9 | 28.4 |

$^a$We report here the values from Table VIII of Ref. 63, last column (+3s3p for $d_c$ and $\omega_e$, and BSSE for $D_e$), from which we subtract the estimated relativistic corrections (RC) for $d_c$, $D_e$ and $\omega_e$ and spin-orbit contributions (SO) for $D_e$. The reported singlet states from our calculations are projected. Please see footnote a of Table III for details.

The reported singlet states from our calculations are spin-projected by the approximate method described in Section 1 (Computational details).

For the results from FSLYP/ECP and Becke98/ECP computations, the splitting between the $(d_{xy}^{A}d_{xy}^{B})$ and $(d_{x^2-y^2}^{A}d_{x^2-y^2}^{B})$ states, both for triplet and for mixed $S_z = 0$, is larger (8 meV for FSLYP/ECP and 4 meV for Becke98/ECP) than the accuracy of the DFT calculations (better than 0.1 meV). Thus, our approximate spin and symmetry projections are questionable for these particular calculations. However, since we observed even larger differences between the components of the $3^2D$ state of Ni (up to 0.03 eV), we chose not to investigate this matter any further. In these cases, the reported values are those of the component with the lowest total energy (largest dissociation energy).

Almost all of our calculations: Becke98 and FSLYP both AE and ECP and B3LYP/AE predict $1(d_{x^2-y^2}^{A}d_{z^2}^{B})$ or $1(d_{xy}^{A}d_{xy}^{B})$ ground state, which is a mixture of $1^\Sigma^+_g$ and $1^\Gamma_g$. B3LYP/ECP predicts a $1(d_{x^2-y^2}^{A}d_{z^2}^{B})$ (mixture of $3^2\Sigma^-_g$ and $3^2\Gamma_u$) ground state virtually degenerate with the $1(d_{x^2-y^2}^{A}d_{z^2}^{B})/1(d_{xy}^{A}d_{xy}^{B})$ state, which is only 1 meV higher in energy than $1(d_{x^2-y^2}^{A}d_{z^2}^{B})$ ground state.

Among the high-level wavefunction methods, CASPT2 without spin-orbit coupling predicts $1^\Sigma^+_g$ ground state degenerate with $1^\Gamma_g$, and CASSCF/IC-ACPF predicts $1^\Gamma_g$ ground state. Our DFT all-electron calculations can be consistent with either one of the wavefunction methods. The experimental results are consistent with any of the predictions of our DFT calculations and CASPT2, but not with the $1^\Gamma_g$ state predicted by CASSCF/IC-ACPF.

The absolute relative deviations from the experimental values of computed bond lengths ($d_c$), dissociation energies ($D_e$) and vibrational frequencies ($\omega_e$) for Ni₂ are plotted in Fig. 4, arranged from left to right in order of decreasing total absolute relative deviation (TARD) — the sum of absolute relative deviations from the experimental values of the computed $d_c$, $D_e$ and $\omega_e$.

From Fig. 4 as well as from Table IV it is apparent that overall, for Ni₂ the all-electron DFT calculations with B3LYP functional give the best agreement with experiment (9.9% TARD), B3LYP/ECP (12.5% TARD) and Becke98/ECP (14.2% TARD) follow with an overall performance just a little better than CASSCF/IC-ACPF (15.3% TARD). Becke98/AE (20.4% TARD) and FSLYP/AE (22.7% TARD) are next among our DFT calculations, performing just a few percent worse than CASPT2 (19.8% TARD). With 44.8% TARD, the FSLYP/ECP calculation gives the largest disagreement with experiment and the other methods.

The relative deviations from the experimental values of the computed bond length ($d_c$), dissociation energy ($D_e$), asymptotic dissociation energy ($D_e^\infty$, vide infra) and vibrational frequency ($\omega_e$) of Ni₂ are plotted in Fig. 4 for comparison. The values are arranged in order of increas-
right in order of decreasing total absolute relative deviation (TARD) — the sum of absolute relative deviations from the experimental value of the computed bond length, $\Delta d$, dissociation energy, $D_e$, and $\omega_e$.

1. Bond length

It is apparent that all calculations included in Table II and Fig. 2 — both our DFT calculations and the CASPT2 [63] and CASSCF/IAACPF [64] wavefunction methods included for comparison — overestimate the bond length of Ni$_2$. The deviations from the experimental value of the computed bond length, $\Delta d = d_{\text{comp}} - d_{\text{exp}}$ range between 0.03 Å (1.5%) and 0.09 Å (4.2%).

Among our DFT calculations, the best agreement with the experiment for the bond length of Ni$_2$ is obtained by FSLYP/ECP with $\Delta d = 0.032$ Å (1.5%), followed by FSLYP/AE with $\Delta d = 0.056$ Å (2.5%) and B3LYP/ECP with $\Delta d = 0.067$ Å (3.0%). Becke98/ECP with $\Delta d = 0.074$ Å (3.4%) performs very similar to CASPT2, for which $\Delta d = 0.077$ Å (3.5%). Both B3LYP/AE and CASSCF/IC-ACPF are among the methods that give the largest disagreement with the experiment, with $\Delta d = 0.087$ Å (3.9%). Finally, Becke98/AE yields the worst deviation from experiment, $\Delta d = 0.092$ Å (4.2%).

Among all three XC functionals, the best agreement with experiment for the bond length is obtained with the FSLYP functional, both AE and ECP. B3LYP follows with a bond length 0.03 Å longer than the one computed with FSLYP. Becke98 bond length is in the worst agreement with the experiment, but only $\approx 0.005$ Å longer than the B3LYP bond length.

2. Dissociation energy

The computed dissociation energies span a large range of values, from 1.33 eV for FSLYP/ECP to 2.07 eV for Becke98/AE. The deviations from the experimental value of the computed dissociation energy, $\Delta D_e = D_{e,\text{comp}} - D_{e,\text{exp}}$ range between $-0.525$ eV ($-28.4\%$) and 0.221 eV (11.9%).

Among our DFT calculations, the best agreement with the experiment for the dissociation energy of Ni$_2$ is obtained with the B3LYP functional. B3LYP/ECP slightly overestimates $D_e$ by 0.001 eV (0.1%), while B3LYP/AE slightly underestimates $D_e$ by 0.015 eV (0.8%). This excellent agreement with the experiment of the B3LYP functional is clearly fortuitous since the errors in the B3LYP dissociation energies average 0.10 eV, with a maximum absolute deviation of 0.36 eV for the G2 set of molecules [65]. Becke98/ECP comes second and underestimates $D_e$ by 0.058 eV (3.1%), performing only slightly worse than CASPT2, which overestimates $D_e$ by 0.040 eV (2.2%). FSLYP/AE is next and it underestimates $D_e$ by 0.186 eV (10.1%) similar to CASSCF/IC-ACPF, for which $\Delta D_e = -0.159$ eV ($-8.6\%$). Becke98/AE and FSLYP/ECP are the methods that give the largest disagreement with the experiment: Becke98/AE overestimates $D_e$ by 0.221 eV (11.9%), and FSLYP/ECP underesti-
mates $D_e$ by 0.525 eV (28.4%). The effects of ECP and XC functionals on the dissociation energy of Ni$_2$ do not seem to show similar trends to the ones seen for the bond length. However, similar trends can be noticed if, instead of $D_e$, one compares the asymptotic dissociation energy, $D_0$, which is the dissociation energy with respect to the $^3D$ atoms that correlate with the ground state of the nickel dimer ($D_e = D_0 + 2E_{Ni} \gamma_d$, where $E_{Ni} \gamma_d$ is the energy of the $^3D$ state of Ni atom relative to the energy of the ground state).

The agreement of computed $D_0$ with the experimental value is clearly better than that of $D_e$. B3LYP/ECP with $\Delta D_0 = -0.015$ eV ($-0.8\%$) and B3LYP/ECP $\Delta D_0 = 0.031$ eV (1.7\%) give the best agreement with the experiment, similar to CASPT2, for which $\Delta D_0$ = 0.040 eV (2.2\%), and FSLYP/AE $\Delta D_0 = 0.052$ eV (2.8\%). FS-LYP/ECP with $\Delta D_0 = 0.106$ eV (5.7\%) is a little worse than FSLYP/AE. Becke98 gives the largest overestimation for $D_0$: Becke98/ACF gives $\Delta D_0 = 0.221$ eV (11.9\%) and Becke98/ECP gives $\Delta D_0 = 0.349$ eV (18.8\%).

For all three functionals, the basis set tends to overestimate the $D_0$ compared to the AE basis. For B3LYP and FSLYP the effect of ECP on $D_0$ is the smallest among the three functionals ($\approx 0.05$ eV), while for the Becke98 functional the effect of ECP on $D_0$ is largest (0.13 eV), for which $\Delta D_0$ increases from 0.22 eV for AE to 0.35 eV for ECP. However, for Becke98/ECP $\Delta D_0$ is only $-0.06$ eV due to cancellation of large and positive $\Delta D_0$ and the large $E_{Ni} (^3D)$. For FSLYP this cancellation doesn’t happen and both FSLYP/AE and FSLYP/ECP underestimate the dissociation energy by fairly large amount because of the large error in $E(^3D \text{ Ni})$.

3. Vibrational frequency

As can be noticed in Fig. 2 there seem to be a general trend for all our DFT calculations, that the error in vibrational frequency decreases as the error in bond length increases. CASSCF/IC-ACPF is close to following the same trend, but CASPT2 is clearly an outlier.

It is apparent that all calculations included in Table III and Fig. 2 — both our DFT calculations and CASPT2 and CASSCF/IAACPF wavefunction methods included for comparison — overestimate the vibrational frequency of Ni$_2$. The deviations from the experimental value of the computed harmonic vibrational frequency, $\Delta \omega_c = \omega_{c,\text{comp}} - \omega_{c,\text{exp}}$, range between $10.6 \text{ cm}^{-1}$ (4.3\%) and $36.8 \text{ cm}^{-1}$ (14.9\%) among our DFT results.

Becke98/ACF with $\Delta \omega_c = 10.6 \text{ cm}^{-1}$ (4.3\%) and B3LYP/ACF $\Delta \omega_c = 12.7 \text{ cm}^{-1}$ (5.2\%) give the best agreement with the experiment among our DFT results, slightly worse than CASSCF/IC-ACPF, for which $\Delta \omega_c = 6.8 \text{ cm}^{-1}$ (2.8\%). Becke98/ECP follows, overestimating $\omega_c$ by 18.9 cm$^{-1}$ (7.7\%), B3LYP/ECP and FSLYP/AE perform similarly with $\Delta \omega_c = 23.1 \text{ cm}^{-1}$ (9.4\%) and $\Delta \omega_c = 24.9 \text{ cm}^{-1}$ (10.1\%), respectively. FSLYP/ECP with $\Delta \omega_c = 36.8 \text{ cm}^{-1}$ (14.9\%) gives the worst agreement with experiment, similar to CASPT2, which overestimates $\omega_c$ by 34.8 cm$^{-1}$ (14.1\%).

4. Summary of the results for $d^4 d_0^6$-holes states of Ni$_2$

All calculations predict $d^4 d_0^6$-holes states to have the lowest energy both for singlet and for triplet spin multiplicities. The bond lengths of optimized geometries, dissociation energies and vibrational frequencies for these states calculated with the described DFT methods are tabulated in Table III for comparison.

The first observation is that the $^3(d^4_{x^2-y^2}d_0^6_{x^2-y^2})$ and/or $^3(d^4_{xy}d_0^6_{xy})$ are the highest-lying states, for all calculations, and that the spin projection changes the ordering of the singlet states for all three all-electron calculations. For these calculations, the lowest energy is obtained for the unprojected singlet $^1(d^4_{x^2-y^2}d_0^6_{x^2-y^2})$ state, and upon projection, the degenerate $^1(d^4_{x^2-y^2}d_0^6_{x^2-y^2})$ and $^1(d^4_{xy}d_0^6_{xy})$ become the ground state.

For the B3LYP/ECP calculation spin projection does not change the $^3(d^4_{x^2-y^2}d_0^6_{x^2-y^2})$ ground state, although it makes the $^3(d^4_{x^2-y^2}d_0^6_{x^2-y^2})$ state nearly degenerate with the degenerate $^1(d^4_{x^2-y^2}d_0^6_{x^2-y^2})$ and $^1(d^4_{xy}d_0^6_{xy})$. However, the $^3(d^4_{x^2-y^2}d_0^6_{x^2-y^2})$ ground state is only 0.001 eV lower in energy than the degenerate $^1(d^4_{x^2-y^2}d_0^6_{x^2-y^2})$ and $^1(d^4_{xy}d_0^6_{xy})$. For Becke98/ECP the unprojected ground state is $^1(d^4_{xy}d_0^6_{xy})$ degenerate with $^3(d^4_{x^2-y^2}d_0^6_{x^2-y^2})$, and upon spin projection, $^1(d^4_{x^2-y^2}d_0^6_{x^2-y^2})$ becomes the ground state, with a dissociation energy larger than the one of $^1(d^4_{xy}d_0^6_{xy})$ by 0.005 eV. For FSLYP/ECP the $^1(d^4_{xy}d_0^6_{xy})$ unprojected ground state does not change upon spin projection, but the difference between the $D_e$ of $^1(d^4_{xy}d_0^6_{xy})$ and $^1(d^4_{x^2-y^2}d_0^6_{x^2-y^2})$ is the largest among all calculations: 0.008 eV, and is larger than the numerical accuracy of the DFT calculations (better than 0.1 meV).

It is also worth noting that for all calculations the average $D_e$ of singlet states is larger than the one of the triplet states. However, the difference between the singlet and the triplet is very small for Becke98/ECP and B3LYP/ECP (0.006 eV and 0.003 eV, respectively). For the other calculations, the difference is somewhat larger, around 0.015 eV.

However, it is important to note from Table III that for each combination of exchange-correlation functional and basis set used, all $\delta$-holes states are in a very narrow energy range: $\approx 20$ meV for all all-electron calculations, 26 meV for FSLYP/ECP, 13 meV for Becke98/ECP and only 7 meV for B3LYP/ECP.

Since, as shown above, the ordering of states can change upon spin-projection, if possible to perform, spin-projection is desirable. However, we want to emphasize that the differences between the lowest broken-symmetry singlet states and the projected singlet ground states,
for the all-electron calculations and FSLYP/ECP, is less than 10 meV, and for some applications that difference may not be relevant. Nevertheless, we plan to consider spin-projection for larger clusters, if possible, at least for evaluating the errors that arise from it.

5. Potential energy curves (PEC)

In order to determine the ground state of Ni$_2$ we did a full scan of the PEC for each method and for each unique combination of holes. All calculations predict δδ-holes states to have the lowest energy, with the next level 50–100 meV above, σδ for Becke98 and B3LYP calculations and πδ for FSLYP calculations.

The computations of σπ states with Becke98 and B3LYP functionals only converge to 10$^{-5}$–10$^{-4}$ Hartree within 100 iterations in the 1.95–2.55 Å range. Because the FSLYP calculations, which converge properly, predict that these states are ≈ 200 meV higher, the same value as the “not-so-converged” results for the above calculations, we have chosen not to investigate the matter any further.

Since the results of the PEC scans are rather similar, and B3LYP is our functional of choice, in the following discussion of the PEC’s, we focus attention principally on the results from B3LYP calculations.

The B3LYP/AE and B3LYP/ECP potential energy curves (PEC) of singlet ($S_z = 0$) and triplet ($S_z = 1$) states of Ni$_2$ (both unrestricted, symmetry broken) are shown in Fig. 3 and in Fig. 4 respectively, along with the variation of $\langle S^2 \rangle$ with the bond length for all possible positions of holes in the 3d shell on both atoms, grouped by hole type. The first trend that can be noticed is that the equilibrium bond length increases as the dissociation energy decreases. Aside for a few states (singlet $\sigma\pi$ and $\pi\pi$), all states have $\langle S^2 \rangle \approx 1$ over a large interval, validating the weakly interacting 3d$^9$ units model for a large range of bond lengths. Even the singlet $\sigma\sigma$ and $\pi\pi$ states have $\langle S^2 \rangle \approx 1$ in a range of about ±1 Å around the equilibrium bond length.

One can notice a big difference between AE and ECP PEC’s: ECP PEC’s branch around 3.5 Å. There are two causes for branching: one, which is not related to functional $\delta$ or ECP, is the restricted–unrestricted crossover, while the other cause is dissociation into $3F$ ground state of Ni atoms. These two effects overlap because the branching is obtained by scanning the PEC from ≈ 3.5 Å, increasing the bond length and using as initial guess the molecular orbitals from the previous calculation. Depending on the initial guess, the calculation may end in the restricted or unrestricted solution, or, at large distances, the calculation may converge to the $3F + 3F$, $3F + 3D$ or $3D + 3D$ states of the Ni atoms. The restricted-unrestricted branching is likely to show up for any of the methods, but the ground-state branching can only appear for the methods that predict $3F$ ground state for Ni, namely FSLYP/AE FS-

| Method     | State                  | $d_c$   | $D_c$   | $\omega_c$ |

FIG. 3: B3LYP/Wachters+f PEC's of Ni$_2$. Energy in eV, relative to ground state Ni atoms and bond length in Å.

FIG. 4: B3LYP/Stuttgart RSC ECP PEC's of Ni$_2$. Energy in eV, relative to ground state Ni atoms and bond length in Å.
LYP/ECP, and Becke98/ECP along with the discussed B3LYP/ECP.

One can also notice that some of the B3LYP/ECP PEC's have asymptotes below 0, i.e., below the energy of the ground state of the two nickel atoms. A closer look reveals that the asymptotes of the $d_{xy}d_{xz}$, $d_{xz}d_{yz}$, $d_{yz}d_{zx}$, $d_{xy}d_{xy}$, $d_{xy}d_{xy}$, $d_{xy}d_{xy}$, $d_{xy}d_{xy}$, $d_{xy}d_{xy}$, $d_{xy}d_{xy}$, and $d_{xy}d_{xy}$-holes states lie 0.1 eV below the ground state of the two nickel atoms, the ones of $d_{z^2}d_{z^2}$, $d_{z^2}d_{z^2}$, $d_{z^2}d_{z^2}$, $d_{z^2}d_{z^2}$-holes states lie 0.04 eV below the ground state of the two nickel atoms, and only $d_{z^2}d_{z^2}$-holes states lie 0.04 eV above the ground state of the two nickel atoms. The most likely explanation for this observation is that B3LYP/ECP predicts a lower energy for a state that is not in the space of states spanned by our initial guess. This issue needs further investigation, but since the effect is rather small (at most 0.05 eV/nickel atom), we chose to investigate the issue in a further paper.

The initial PEC scans are done either with broken symmetry atomic initial guess (3$d^3$4$s^1$ $\uparrow\uparrow\uparrow$ + $\uparrow\downarrow\downarrow$ 3$d^3$4$s^1$ for singlet and 3$d^3$4$s^1$ $\uparrow\uparrow\downarrow$ + $\downarrow\uparrow\uparrow$ 3$d^3$4$s^1$ for triplet) at each bond length or, starting from 10 Å and decreasing the bond length and using as initial guess the molecular orbitals at the previous bond length. Either initial guess gives the same results, but the method using atomic initial guess needs a few extra iterations. For larger cluster calculations it may be useful to save the molecular orbitals at each geometry configuration and try to reuse them for a neighboring point calculation.

It is apparent from Fig. 3 that for the B3LYP/AE calculation the singlet dissociates to the correct 2$^1D$ atoms limit ($\langle S^2 \rangle = 2$), whereas the triplet dissociates to 3$^D + 1^3D$, which is 0.14 eV above the correct limit. This type of error only plays an important role at large distances; when the molecule starts to resemble two separated atoms, and can be correlated with $\langle S^2 \rangle$ of the Kohn-Sham determinant. When $\langle S^2 \rangle$ is close to the exact value, this type of error is not present. For Ni$_2$, both singlet and triplet, the $\langle S^2 \rangle$ is correct (i.e., equal to the theoretical value) for 2 Å < $d_e$ < 3 Å. At interatomic distances greater than approximately 3 Å, $\langle S^2 \rangle$ starts to increase, and so does the error in the energy of the triplet. At interatomic distances larger than approximately 4 Å, $\langle S^2 \rangle$ for the triplet reaches a value of $\approx$ 3 and stays constant for larger distances. Similarly, the error in the energy of the triplet approaches the asymptotic value of 0.14 eV.

In larger clusters, this could be a potential issue for computing barriers. However, only configurations in which one atom is at sufficiently large distance from other atoms, completely or partly detached (evaporated) from the cluster, and in the 1$^3D$ state, would encounter the above described problem. Moreover, the error ($\leq$ 0.14 eV) could be important if the height of the barrier were small. But the evaporation energy of an atom from the cluster is likely to be of the same order of magnitude as the dissociation energy of the dimer ($\approx$ 1.5 eV), and the height of the barrier would be overestimated by $\approx$ 10%. Consequently, this error should be unimportant for large clusters.

C. Nickel Hydride

The bond lengths ($d_e$), dissociation energies ($D_e$), vibrational frequencies ($\omega_e$) and dipole moment ($\mu$) for ground states of NiH from different calculations are reported in Table IV along with experimental values and results from other theoretical studies, listed in the order of decreasing average of absolute relative deviations (AARD) from the experimental values of the computed $d_e$, $D_e$, $\omega_e$ and $\mu$.

The experimental values reported in Table IV are the unperturbed values of $d_e$ and $\omega_e$ of Gray et al. [70], cited in Ref. 63, the recommended value of $D_e$ from Ref. 71 (cited in Ref. 63) and $\mu$ from Ref. 72 (cited in Ref. 63), from which we subtract the CASPT2 relativistic corrections (RC) to $d_e$, $D_e$, and $\mu$ from Ref. 63, and the MRCl RC to $\omega_e$ from Ref. 63 (see footnote a of Table IV for details).

The absolute relative deviations from the experimental values of the computed bond lengths ($d_e$), dissociation energies ($D_e$), vibrational frequencies ($\omega_e$) and dipole moment ($\mu$) of the ground state of NiH are plotted in Fig. 5 for comparison. They are arranged from left to right in order of decreasing total absolute relative deviation (TARD) — the sum of absolute relative deviations from the experimental values of the computed $d_e$, $D_e$, $\omega_e$ and $\mu$. 

![Figure 5](image_url)
TABLE IV: Ground state of NiH — comparison between computations and experiment. \( d_e \) — bond length (\( \text{Å} \)), \( D_e \) — dissociation energy, relative to ground state Ni atoms (without zero-point correction, eV), \( \omega_e \) — vibrational frequency (cm\(^{-1}\)) and \( \mu \) — dipole moment (Debye). The relative errors with respect to experimental values are given in parentheses, and the average (AARD) and the maximum (MARD) absolute relative deviations from experimental values of \( d_e, D_e, \omega_e \) and \( \mu \) are listed under the AARD and MARD columns, respectively.

| Method       | \( d_e \) (\%a) | \( D_e \) (\%b) | \( \omega_e \) (\%c) | \( \mu \) (\%d) | AARD (\%e) | MARD (\%f) |

\(a\) We report here the values from Table VI of Ref. [63] for \( d_e, D_e \) and \( \omega_e \), and from Table VII for \( \mu \) [PT2F(3x3p)+RC], from which we subtract the estimated relativistic corrections (RC). From the same reference, we estimate the RC to \( d_e \) and \( D_e \) from Table V and the RC to \( \mu \) from Table VII, as the difference between the PT2F+RC values and the PT2F ones. We use the MRCI RC to \( \omega_e \) from Ref. [63] We also subtract these relativistic corrections from the experimental values.

\(b\) Experimental values from which we subtract the CASPT2 relativistic corrections (RC) to \( d_e, D_e \) and \( \mu \) from Ref. [63], and the MRCI RC to \( \omega_e \) from Ref. [69] (see footnote a). The experimental value of \( d_e \) is 1.454 \( \text{Å} \) [71, cited in Ref. 63], from which we subtract the CASPT2 RC of \(-0.023 \text{Å}\); the experimental value of \( D_e \) is 2.70 eV [recommended value from Ref. 71, cited in Ref. 63], from which we subtract the CASPT2 RC of 0.15 eV; the experimental value of \( \omega_e \) is 2001.3 cm\(^{-1}\) [70, cited in Ref. 63], from which we subtract the MRCI RC of 60 cm\(^{-1}\); the experimental value of \( \mu \) is 2.4 ± 0.1 Debye [72], from which we subtract the CASPT2 RC of \(-0.22\) Debye.

From Fig. 4 as well as from Table IV it is apparent that for NiH, the best overall agreement with experiment among our DFT calculations is obtained for FSLYP/ECP (7.9 % TARD), followed by Becke98/AE (14.4 % TARD) and FSLYP/AE (16.9 % TARD) similar to CASPT2 (16.4 % TARD). B3LYP/AE (19.3 % TARD) is next, similar to Becke98/ECP (19.4 % TARD), and B3LYP/ECP (28.3 % TARD) gives the largest disagreement with experiment.

All our DFT calculations predict \( \Delta \) (\( \delta \)-hole) ground state, in agreement with the CASPT2 calculation and experiment. However, it is important to note, that, for Becke98/ECP and FSLYP/ECP the result shows the difference between the \( d_{2\pi} \)-hole and the \( d_{2\pi}-\gamma \)-hole components of the \( \Delta \) state — 2 meV and 5 meV, respectively — is larger than the error of the DFT calculations (\( \leq 0.1 \) meV). We report the energy of the component with the lowest energy as the energy of the ground state.

It is apparent that all calculations included in Table IV and Fig. 6 underestimate the bond length of NiH. Becke98/AE with \( \Delta d_e = d_{\text{comp}}^{\text{exp}} - d_{\text{exp}}^{\text{exp}} = -0.0003 \text{Å} \) (−0.02 %) gives the best agreement with experiment. The other DFT calculations and CASPT2 give significantly shorter bond lengths for NiH than Becke98/AE, but they can still be considered in good agreement with the experiment, giving \( \Delta d_e \) ranging from \(-0.003 \text{Å} \) (−0.2 %) for B3LYP/AE to \(-0.025 \text{Å} \) (−1.9 %) for FSLYP/ECP. Among all three XC functionals, the best agreement with experiment for the bond length is obtained with the Becke98 functional, both AE and ECP. B3LYP follows with a bond length 0.003 Å shorter than the one computed with Becke98. FSLYP bond length is in the worst agreement with the experiment, but only \( \approx 0.004 \text{Å} \) longer than the B3LYP bond length. For each of the three XC functionals used, ECP calculation predicts shorter bond length than the AE one by \( \approx 0.02 \text{Å} \), like in the case of Ni\(_2\), but this worsens the agreement with the experiment, unlike in the case of Ni\(_2\).

The computed dissociation energies span a large range of values, from 2.53 eV for FSLYP/ECP to 2.90 eV for B3LYP/ECP. Among all DFT computations, only FS-
LYP/ECP underestimates $D_e$ by 0.024 eV (0.9 %), and gives the best agreement with the experiment. All other DFT computations and CASPT2 overestimate $D_e$: FSLYP/AE by 5 %, CASPT2 by 8 %, and Becke98/ECP, B3LYP/AE, Becke98/AE, and B3LYP/ECP by 10 %, 12 %, 13 %, and 14 %, respectively, giving the largest disagreement with experiment. Like in the case of Ni$_2$, he effects of ECP and XC functionals on the dissociation energy of Ni$_2$ do not seem to show similar trends to the ones seen for the bond length. It can be verified that trends show up upon correcting $D_e$ with the energy of the $^3D$ state of Ni, but, since for Ni there is no physical ground for that kind of correction, we chose not to do it. However, it is worth noting that the errors in the atomic energies have such large influence on the energetics of molecules.

The differences in the theoretical harmonic vibrational frequencies compared to the experimental values are less than 1 % for our DFT calculations, while CASPT2 has the largest difference from the experimental value among the results plotted in Fig. 6 and listed in Table IV, and a comparison of the theoretical and experimental values of the dipole moment listed in Table IV and plotted in Fig. 6 shows that Becke98/AE gives the best agreement, similar to CASPT2. B3LYP/AE underestimates the dipole moment by 7 % and FSLYP/AE overestimates it by a large amount (11 %). ECP have a strong effect on $\mu$, lowering its value by $\approx 0.15 \, D$ (6 %), bringing FSLYP/ECP in closer agreement with experiment and worsening the agreement for B3LYP and Becke98. It is worth noting that Becke98 predicts a value for $\mu$ in better agreement with the experiment than B3LYP. Since $\mu$ is a one-electron property, this may be an indication that Becke98 gives a more accurate ground state electron density.

**IV. CONCLUSION**

We have used DFT with hybrid exchange-correlation functionals in the broken-symmetry unrestricted formalism to study the electronic structure of nickel dimer and nickel hydride as model systems for larger bare/hydrogenated nickel clusters. We have examined three hybrid functionals: the popular B3LYP, Becke’s newest optimized functional Becke98, and the simple FSLYP functional (50 % Hartree-Fock and 50 % Slater exchange and LYP gradient-corrected correlation functional) with two basis sets: all-electron (AE) Wachters+f basis set and Stuttgart RSC effective core potential (ECP) and basis set.

For Ni$_2$, all of our DFT calculations give bond lengths that are within 0.1 Å (5 %) from the experimental value, and in good agreement with the high-level wavefunction methods CASPT2[61] and CASSCF/IC-ACPF[62]. Only Becke98/AE and B3LYP/AE give harmonic vibrational frequencies that are within 5 % from the experimental value, similar to CASSCF/IC-ACPF. Becke98/ECP, B3LYP/ECP and FSLYP/AE give $\omega_e$ within 10 % from the experimental value, similar to CASPT2, and FSLYP/ECP overestimates the experimental $\omega_e$ by 15 %. The discrepancies between calculated and experimental values of dissociation energy span a large range, between $-28$ % and 12 %. B3LYP/ECP, B3LYP/AE and Becke98/ECP give values of $D_e$ that are within less than 5 % from the experimental value, similar to CASPT2. FSLYP/AE and Becke98/AE give values of $D_e$ that are a within 12 % from experimental value, similar to CASSCF/IC-ACPF. FSLYP/ECP gives a value of $D_e$ that is smaller than the experimental value by 28 %.

For NiH, all of our DFT calculations give bond lengths that are within 0.03 Å (2 %) from the experimental value, and in good agreement with CASPT2[63]. They also give harmonic vibrational frequencies that are within less than 15 cm$^{-1}$ (1 %) from the experimental value, in better agreement with experiment than CASPT2, which overestimates $\omega_e$ by 4 %. The discrepancies between the calculated and the experimental values of dissociation energy span a large range for NiH like they do for Ni$_2$. FSLYP/ECP underestimates $D_e$ by 1 %, giving the best agreement with the experiment. All other DFT calculations and CASPT2 overestimate $D_e$ by amounts between 5 % and 15 %. For the dipole moment the deviations from the experimental value span the largest range: between $-13$ % for B3LYP/ECP and 11 % for FSLYP/AE. Underestimating it by 1 %, Becke98/AE gives the best agreement with the experiment for the dipole moment of NiH, similar to CASPT2, which underestimates it by 3 %.

We also find that for Ni$_2$, the spin-projection for the broken-symmetry unrestricted singlet states changes the ordering of the states, but the splittings are less than 10 meV. All our calculations predict a $\delta$-hole ground state for Ni$_2$ and $\delta$-hole ground state for NiH. Upon spin-projection of the singlet state of Ni$_2$, almost all of our calculations: Becke98 and FSLYP both AE and ECP and B3LYP/AE predict $1(d_{z^2}^A d_{xy}^B)$ or $1(d_{z^2}^A d_{xy}^B)\Gamma_g$ ground state, which is a mixture of $1\Sigma_g^+$ and $1\Gamma_g$. B3LYP/ECP predicts a $3(d_{xy}^A d_{x^2-y^2}^B)$ (mixture of $3\Sigma_g^-$ and $3\Gamma_u$) ground state virtually degenerate with the $1(d_{z^2}^A d_{xy}^B)\Gamma_u$ state, which is only 1 meV higher in energy than $3(d_{xy}^A d_{x^2-y^2}^B)$ ground state. The doublet $\delta$-hole ground state of NiH predicted by our calculations is in agreement with the experimentally predicted $2\Delta$ ground state. For Ni$_2$, all our results are consistent with the experimentally predicted ground state of $0_2^+$ (a mixture of $1\Sigma_u^+$ and $3\Sigma_u^-$) or $0_2^-$ (a mixture of $1\Sigma_u^+$ and $3\Sigma_u^-$).

The goal of this paper is to establish what might comprise a minimally reliable method for more extensive nickel cluster calculations. Since none of the studied methods gives a good agreement with experiment for all computed molecular properties of Ni$_2$ and NiH, we de-
where $i$ runs over all 7 computed molecular properties for Ni$_2$ and NiH ($d_e$, $D_e$ and $\omega_c$ of both Ni$_2$ and NiH, and $\mu$ of NiH); $\epsilon_i$ is the relative deviation from the experimental value of the molecular property $i$; $i < j$ stands for $i,j$ running over all 21 unique pairs.

The overall discrepancy $Q$ is the sum of two contributions: the average discrepancy $Q_A$, which measures the overall (average) deviation of the computed molecular properties from the experimental values, and the consistency $Q_D$, which measures the consistency of the methods both when computing different molecular properties of the same molecule (e.g. $d_e$, $D_e$ and $\omega_c$ of both Ni$_2$ and NiH), and when computing molecular properties for different molecules (e.g. $d_e$ of Ni$_2$ and $d_e$ of NiH). For analysis, we calculate each of the indicators $Q$, $Q_A$ and $Q_D$ for each of the molecules, by partitioning Eq. (4) into the components for Ni$_2$ ($Q^{\text{Ni}_2}$, $Q_A^{\text{Ni}_2}$, and $Q_D^{\text{Ni}_2}$), the components for NiH ($Q^{\text{NiH}}$, $Q_A^{\text{NiH}}$, and $Q_D^{\text{NiH}}$), and the mixed components of $Q_D$, $Q_D^{\text{Ni}_2-\text{NiH}} = \frac{1}{21} \sum_{i,j} |\epsilon_i - \epsilon_j|$ with $i$ running over the molecular properties of Ni$_2$ and $j$ running over the ones of NiH.

In Fig. 7 we plot the overall discrepancy $Q$ along with its components, and the maximum absolute deviations from experimental values (MARD) for all computed molecular properties of Ni$_2$ ($\Delta^{\text{Ni}_2}_{\text{max}}$) and NiH ($\Delta^{\text{NiH}}_{\text{max}}$).

APPENDIX A: ACCURACY OF CHARGE DENSITY FITTING

As stated in Section II we use charge density fitting for the calculations using the all-electron Wachters+f basis set, for which we employ the Ahlrichs Coulomb Fitting 52,53 basis set. For evaluating the error introduced by charge density fitting we perform the atomic computations with B3LYP functional and Wachters+f basis set with and without charge density fitting. The charge density fitting lowers the total energies of computed atomic states by 2–3·10$^{-4}$ Hartree. The errors in the relative energies are less severe, ranging from ~3.8 to 1.5 meV.

To be cautious, we have investigated this issue further by comparing results of geometry optimizations and frequency calculations on the 12 ($d_0^2 d_1^0$) states of Ni$_2$ (six singlet, broken symmetry, and six triplet) with B3LYP/AE functional both with and without charge density fitting. The results are summarized in Table VII. Although the errors in total energies are rather large (on the order of a little less than 1 mHartree, as can be seen in column labeled $E_e$/mHartree in Table VII, they all have the same sign, averaging ~0.6476±0.0018 mHartree.

Moreover, the errors in the relative energies (with respect to the ground state Ni atom, labeled $E_e$/meV in Table VI) are much smaller (~5 meV), and again all with the same sign. Finally, the relative ordering of the states is correct, and the root-mean-square of the relative energies with respect to the lowest energy state from each calculation, labeled $\Delta E_e$/meV in Table VII, is 0.03 meV with a maximum of 0.12 meV. The maximum error due to charge density fitting to be expected in exploring the PES’s of larger clusters is on the order of 2–3 meV per Ni atom.

As stated in Section II we did not use charge density fitting with ECP because of the large errors that resulted when we tried the use of Ahlrichs Coulomb Fitting basis in combination with Stuttgart RSC ECP. In Table VII we report the errors in the bond lengths ($d_e$), dissociation energies ($D_e$), and harmonic vibrational frequencies ($\omega_e$) of Ni$_2$ and NiH, and dipole moment ($\mu$) computed with B3LYP and FSLYP functionals using “Stuttgart RSC ECP” ECP and basis set with “Ahlrichs Coulomb Fitting” basis. The errors in bond lengths are negligible for both Ni$_2$ and NiH, but the errors in the vibrational frequencies of both Ni$_2$ and NiH, dipole moment of NiH and dissociation energy of NiH, of the order of 5%, are significant. The error in the dissociation energy of Ni$_2$ is large, ~0.3 eV (~16%) for B3LYP and ~0.33 eV (~25%) for FSFLYP.

APPENDIX B: ACCURACY AND CONVERGENCE ISSUES OF DFT COMPUTATIONS

The numerical integration necessary for the evaluation of the exchange-correlation energy implemented in NWChem uses an Euler-MacLaurin scheme for the radial components (with a modified Mura-Knowles transformation) and a Lebedev scheme for the angular components. Table VIII lists the grid details for the three levels of accuracy for the numerical integration that are used in our DFT calculations, labeled by the corresponding keywords from NWChem (medium, fine and xfine). In the same table we list convergence criteria used for each level of
In order to assess the errors arising from numerical integration we have performed a series of computations using different predefined grid schemes available in NWChem. First, we have performed the atomic calculations using both $x_{fine}$ and $fine$ grids. The differences are of the order of total energy target accuracy of the $fine$ grid ($\approx 1.5 \cdot 10^{-7}$ Hartree). We have also compared the all-electron DFT computations using B3LYP functional with $fine$ grid against the ones with $x_{fine}$ grid for geometry optimization and frequency calculations for Ni$_2$, $(d^{A}_{x^2-y^2}d^{B}_{xy})$ singlet and triplet states. The differences are on the order of $10^{-4}$ Å for equilibrium bond length, $2 \cdot 10^{-6}$ Hartree for total equilibrium energy and $0.2$ cm$^{-1}$ for vibrational frequency. We conclude that the $fine$ grid is appropriate for geometry optimization and vibrational frequency calculations, and have used it in the present work. For the potential energy curve (PEC) scans we use the $medium$ grid, which gives for a 19-point B3LYP/AE PEC scan in the range $2...3.2$ Å of Ni$_2$ $(d^{A}_{x^2-y^2}d^{B}_{xy})$ singlet an error in energy of 16 µeV (maximum) and 1.4 µeV (root-mean-square) with respect to the $fine$ grid computations.
