We study a class of growth processes in which clusters evolve via exchange of particles. We show that the rate of exchange there are three possibilities: I) Growth: Clusters grow indefinitely; II) Gelation: All mass is transformed into an infinite gel in a finite time; and III) Instant Gelation. In regimes I and II, the cluster size distribution attains a self-similar form. The large size tail of the scaling distribution is \( \Phi(x) \sim \exp(-x^{2-\nu}) \), where \( \nu \) is a homogeneity degree of the rate of exchange. At the borderline case \( \nu = 2 \), the distribution exhibits a generic algebraic tail, \( \Phi(x) \sim x^{-5} \). In regime III, the gel nucleates immediately and consumes the entire system. For finite systems, the gelation time vanishes logarithmically, \( T \sim [\ln N]^{-\nu} \), in the large system size limit \( N \to \infty \). The theory is applied to coarsening in the infinite range Ising-Kawasaki model and in electrostatically driven granular layers.

I. INTRODUCTION

A multitude of growth phenomena in physical processes are driven by exchange of particles between clusters. Examples include droplet growth via evaporation and re-condensation \( [1] \), island growth in deposition processes \( [2] \), and phase ordering \( [3, 4] \). Exchange processes have been also used to model social and economical systems including segregation of heterogeneous populations \( [5] \), the distribution of wealth in a society \( [6] \), and growth of urban populations \( [7, 8, 9] \).

In exchange processes, clusters are composed of ‘atoms’ (monomers). Monomers detach from one cluster and re-attach to another cluster. We shall consider the detachment controlled limit where the time scale for transport between clusters is much faster then the time scale for detachment. Exchange processes incorporate both reversible and irreversible features. Clusters may grow or shrink, yet when a monomer attaches to another cluster, its respective cluster disappears. This irreversible step provides the mechanism for cluster growth. Therefore, exchange-driven processes are fundamentally different from irreversible growth processes, particularly aggregation \( [10, 11, 12] \).

Such mass transfer processes are governed by an exchange kernel \( K(i,j) \) that represents the rate of transfer of monomers from a cluster of size \( i \) to a cluster of size \( j \). Generally, the rate of monomer exchange between two clusters depends on their sizes. Moreover, we consider the case where there is no preferable direction for exchanges, i.e., symmetric exchange kernels, \( K(i,j) = K(j,i) \). This is unlike migration processes where the exchange is preferential (“big gets bigger” or “rich gets richer”). Migration underlies certain physical processes (e.g., coarsening with conserved order parameter \( [3, 4] \)) as well as social and economical processes \( [7, 8, 9] \).

We investigate homogeneous exchange kernels, \( K(ai,aj) = a^{2\lambda}K(i,j) \). In particular, we consider the product kernel \( K(i,j) = (ij)^\lambda \) and its generalization \( K(i,j) = i^\nu j^\mu + i^\mu j^\nu \) with \( \nu + \mu = 2\lambda \) and \( \nu \geq \mu \). We obtain a complete description of the problem in the asymptotic scaling regime. The overall range of possible behaviors and the emergence of self-similar size distributions are as in aggregation and migration processes. However, there are quantitative and qualitative differences. Unlike aggregation, the gelation transition is complete, and unlike migration, the size distributions are extended rather than compact.

The behavior falls into three categories. I) Growth: When \( \nu < 2 \) and \( \lambda < 3/2 \), clusters grow indefinitely. The typical cluster size grows algebraically with time, \( k \sim t^{1/(3-2\lambda)} \), and the cluster size distribution is given by a self-similar distribution with a stretched exponential tail. II) Gelation: When \( \nu < 2 \) and \( \lambda > 3/2 \), the entire mass in the system is transformed into an infinite gel in a finite time. The cluster mass diverges algebraically near the gelation point, \( k \sim (t_c - t)^{1/(3-2\lambda)} \) and a scaling behavior similar to the one underlying the growth phase is found. In the borderline case \( \nu = 2 \) the scaling function has an algebraic tail with a universal exponent \( \Phi(x) \sim x^{-5} \). Scaling breaks down in the special point \( \nu = \mu = 2 \) where the distribution is log-normal. III) Instant gelation: When \( \nu > 2 \), the gelation time vanishes logarithmically with the system size, \( t_c \sim [\ln N]^{-\nu} \). In particular, for an infinite system, gelation is instantaneous.

This paper is organized as follows. In the next section, we define the exchange process. The governing equations are analyzed using scaling techniques and exact solutions.

*Electronic address: ebn@lanl.gov

for the moments. We first analyze the product kernel (Sec. III) and then, the generalized kernel (Sec. IV). The gelation time in finite systems is investigated in Sec. V using heuristic arguments and numerical simulations. Applications to coarsening in the Ising model with infinite range Kawasaki dynamics and in electrostatically driven granular layers are briefly discussed in Sec. VI, and conclusions are given in Sec. VII.

II. EXCHANGE PROCESSES

We consider the following elementary exchange process. The system consists of an ensemble of clusters and clusters evolve via transfer of a single monomer from one cluster to another. Symbolically,

\[ (i, j) \xrightarrow{K(i,j)} (i \pm 1, j \mp 1) \]

with \( i \) and \( j \) the number of particles in each cluster and \( K(i,j) \) the exchange kernel. In an exchange event, a cluster is equally likely to gain or to lose a particle. Since the exchange process is unbiased, the matrix of transition rates is symmetric: \( K(i,j) = K(j,i) \).

Let \( A_k(t) \) be the density of clusters containing \( k \) monomers at time \( t \). It evolves according to the following rate equation

\[
\frac{dA_k}{dt} = \sum_{i,j} A_i A_j K(i, j) [\delta_{k,i+1} + \delta_{k,i-1} - 2\delta_{k,i}] .
\]

(2)

This equation assumes perfect mixing, or equivalently, absence of spatial correlations. We restrict our attention to monodisperse initial conditions, \( A_k(0) = \delta_{k,1} \). The exchange process has a single conservation law. As reflected by the evolution equations, the total mass is conserved, \( M_1 = 1 \) with \( M_n = \sum_k k^n A_k(t) \) the moments of the size distribution. It is natural to consider homogeneous kernels, \( K(ai, aj) = a^{2\lambda} K(i, j) \) with \( 2\lambda \) the homogeneity degree and we present results for the product kernel \( K(i, j) = (ij)^\lambda \) and the generalized homogeneous kernel

\[
K(i, j) = i^{\nu} j^{\mu} + i^{\mu} j^{\nu} \text{ with } \mu + \nu = 2\lambda.
\]

III. THE PRODUCT KERNEL

For the product kernel, \( K(i, j) = (ij)^\lambda \), the rate equations read

\[
\frac{dA_k}{dt} = M_\lambda \left[ (k + 1)^\lambda A_{k+1} + (k - 1)^\lambda A_{k-1} - 2k^\lambda A_k \right]
\]

with the boundary condition \( A_0 = 0 \). These evolution equations demonstrate the diffusive character of the exchange process. Absorbing the factor \( M_\lambda \) into the time variable

\[
\tau = \int_0^t dt' M_\lambda(t')
\]

we recast the governing equations into

\[
\frac{dA_k}{d\tau} = (k + 1)^\lambda A_{k+1} + (k - 1)^\lambda A_{k-1} - 2k^\lambda A_k .
\]

(4)

Alternatively, one can study integer moments of the size distribution. The total density obeys \( \frac{d}{d\tau} M_1 = -A_1 \), the total mass is conserved \( \frac{d}{d\tau} M_1 = 0 \), and higher integer moments satisfy the following hierarchy of equations

\[
\frac{d}{d\tau} M_n = 2 \sum_{l=1}^{[n/2]} \binom{n}{2l} M_{n-2l+1} .
\]

(5)

Only for integer values of the homogeneity index is this hierarchy closed. We employ different approaches for different \( \lambda \)’s. For \( \lambda < 2 \), we perform a scaling analysis of the rate equations and for \( \lambda \geq 2 \), we analyze the moment equations. This general analysis is augmented by exact solutions for the integer values \( \lambda = 0, 1, \) and 2.

A. Scaling (\( \lambda < 2 \))

When \( \lambda < 2 \), dimensional analysis of Eq. (4) shows that the typical cluster size grows as

\[ k \sim \tau^\alpha, \quad \text{with} \quad \alpha = \frac{1}{2 - \lambda} .\]

(6)

Using \( \frac{d\tau}{dt} = M_\lambda \sim \tau^{\alpha(\lambda-1)} \), the growth of the typical scale is expressed in terms of the physical time

\[ k \sim \begin{cases} t^\beta & \lambda < 3/2, \\ \exp(\text{const} \times t) & \lambda = 3/2, \\ (t_c - t)^\beta & 3/2 < \lambda < 2. \end{cases} \]

(7)

The dynamical exponent is \( \beta = (3 - 2\lambda)^{-1} \). As long as \( \lambda < 3/2 \), clusters grow indefinitely and the characteristic size grows algebraically with time. For \( \lambda > 3/2 \), a gelation transition occurs, i.e., the system develops a giant cluster in a finite time \( t_c \).

We seek a scaling solution of the rate equations

\[ A_k(\tau) \sim \tau^{-2\alpha} \Phi(\kappa^{\tau-\alpha}) . \]

(8)

Mass conservation dictates the normalization \( J_1 = 1 \) where \( J_n = \int dx x^n \Phi(x) \) is the \( n \)th moment of the scaling distribution. Technically, the scaling function describes the behavior in the limits \( k \to \infty, \tau \to \infty \) with the variable \( x = k^{1-\alpha} \) fixed. Thus, we consider the continuum limit of the rate equation \( \frac{d}{d\tau} A(k, \tau) = \frac{d^2}{d\tau^2} [k^{\lambda} A(k, \tau)] \). The scaling function satisfies the second order linear differential equation

\[ (2 - \lambda) \frac{d^2}{dx^2} [x^{\lambda} \Phi(x)] + x \frac{d}{dx} \Phi(x) + 2\Phi(x) = 0 . \]

(9)

Multiplying this equation by \( x \), employing the identities \( x^2 \Phi' + 2x \Phi = (x^2 \Phi)' \), \( x \Phi'' = (x \Phi)' - 2\Phi' \), and integrating once yields \( (2 - \lambda) [(x^{\lambda+1} \Phi) - 2x^2 \Phi] + x^2 \Phi(x) = 0 . \)
Integrating a second time gives the scaling function:

\[ \Phi(x) = C x^{1-\lambda} \exp \left[ -\frac{x^{2-\lambda}}{(2-\lambda)^2} \right] \]  

(10)

with \( C = (2-\lambda)^{-2/(2-\lambda)}/\Gamma \left( \frac{1}{2-\lambda} \right) \) found from the condition \( J_1 = 1 \). The nature of the scaling function differs from that found for migration where \( K(t,m) = 0 \) for \( l < m \) [8]: Exchange is characterized by extended distributions, while migration is characterized by compact distributions.

There are two physically relevant cases for which the rate equations can be solved exactly. When the exchange kernel is independent of the cluster size (\( \lambda = 0 \)), the rate equation is

\[ \frac{d}{dt}A_k = A_k^{k+1} + A_{k-1} - 2A_k \]

and the cluster size distribution is

\[ A_k = e^{-2\tau} [I_{k-1}(2\tau) - I_{k+1}(2\tau)] \]

(11)

where \( I_n \) is the modified Bessel function of order \( n \). In agreement with the general scaling analysis, the typical scale grows diffusively, \( k \sim \tau^{1/2} \), and the scaling function is given by \( \Phi(x) = (4\pi)^{-1/2} \exp(-x^2/4) \).

For the pure product kernel (\( \lambda = 1 \)), the rate equations read

\[ \frac{d}{dt}A_k = (k+1)A_{k+1} + (k-1)A_{k-1} - 2kA_k \]

in this case \( \tau = t \). Substituting the mass-conserving ansatz \( A_k = (1-u)^2 u^{k-1} \) reduces the infinite set of rate equations into a single ordinary differential equation

\[ \frac{d}{dt}u = (1-u)^2 \]

subject the initial condition \( u(0) = 0 \). The size distribution in this case is

\[ A_k = \frac{t^{k-1}}{(1+t)^{k+1}}. \]

(12)

The typical cluster size grows ballistically, \( k \sim t \), and the scaling function is purely exponential, \( \Phi(x) = x^{-\tau} \), in agreement with the above scaling results.

When \( 3/2 < \lambda < 2 \), an infinite cluster is formed at some finite time \( t_c \) termed the gelation time. The gelation time depends on the initial condition and its determination requires the full time dependent behavior. Even without knowing the gelation time exactly, one can describe the behavior in the pre-gel stage since the size distribution still admits the scaling form. Thus, for all \( \lambda < 2 \) we have

\[ A_k(\tau) \approx C k^{1-\lambda} \tau^{-k} \exp \left[ -\frac{k^2-\lambda}{2(2-\lambda)} \right] \]

implying that \( A_k \to 0 \) in the limit \( \tau \to \infty (t \to t_c) \).

In other words, the gelation is complete, \( A_k(t) = 0 \), for \( t \geq t_c \). This behavior differs from aggregation processes where at the gelation time, all mass in the system is contained in finite size clusters.

Complete gelation can be alternatively shown as follows. Let us assume that the cluster size distribution approaches a constant \( A_k \to A_k^* \) as \( \tau \to \infty \). From Eqs. 4, the quantities \( B_k = k^\lambda A_k^* \) satisfy the discrete Laplace equation

\[ B_k + B_{k+1} - 2B_k = 0 \]

for \( k > 1 \) and \( B_2 = 2B_1 \). Solving recursively yields \( B_k = kB_1 = kA_1^* \) or \( A_k^* = k^{1-\lambda} A_1^* \). Mass conservation, \( \sum_k kA_k^* = 1 \), implies \( A_1^* = 0 \), and thence \( A_k^* = 0 \) for all \( k \), i.e., complete gelation.

### B. Multiscaling (\( \lambda = 2 \))

In this special case, the moment equations [5] are closed for \( n \geq 2 \). For example

\[ \frac{dM_2}{dt} = 2M_2, \quad \frac{dM_3}{dt} = 6M_3, \quad \frac{dM_4}{dt} = 12M_4 + 2M_2. \]

(14)

The solutions to these equations are combinations of exponentials:

\[ M_2 = \exp(2t)^{-1}, \quad M_3 = \exp(2t)^{-3}, \quad M_4 = \exp(2t)^{-5} - \frac{1}{2} \exp(2t)^{-1}. \]

Therefore, the gelation time is \( t_c = 1/2 \). Asymptotically, the first term in [5] dominates: \( \frac{d}{dt}M_n \sim n(n-1)M_n \) implying \( M_n \sim \exp[n(n-1)/2] \) for \( n > 1 \). Close to the gelation time \( (t \to t_c) \), the moments diverge according to

\[ M_n(t) \sim (t_c - t)^{-n(n-1)/2}. \]

(16)

In this special case, moments exhibit multiscaling asymptotic behavior, namely, the normalized moments \( M_n^{1/n}/M_1 \) diverge.

To determine the asymptotic form of the size distribution we treat \( k \) as a continuous variable. For \( \lambda = 2 \), Eq. 4 becomes

\[ \frac{d}{dt}A_k - \frac{d}{d\xi} \left[ k^2 A_k \right] \]

and \[ \frac{d}{d\xi} \] is thereby suggesting use of the variable \( \xi = \ln \) instead of \( k \). Making the transformation from \( A_k(t) \) to \( A(\xi, \tau) \) defined via \( d\xi = d(k^1) \), we cast above equation for \( A_k(t) \) into the following constant coefficients diffusion-convection equation

\[ \left( \frac{\partial}{\partial \tau} - \frac{\partial}{\partial \xi} \right) A(\xi, \tau) = \frac{\partial^2}{\partial \xi^2} A(\xi, \tau). \]

(17)

With the initial conditions \( A(\xi, 0) = \delta(\xi) \), the solution reads \( A(\xi, \tau) = (4\pi\tau)^{-1/2} \exp(-\xi^2/(4\tau)) \). The original distribution \( A_k = k^{-1} A(\xi) \) is log-normal

\[ A_k(\tau) \approx (4\pi\tau)^{-1/2} e^{-\tau/4} k^{-3/2} \exp \left[ -\frac{(\ln k)^2}{4\tau} \right]. \]

(18)

Again, the distribution vanishes at the transition point, i.e., the gelation transition is complete. Moreover, the
mass conservation, \(A_k(t) \sim M_0(t) k^{-3/2}\) for sufficiently small masses, \(k \ll \sqrt{\ln \frac{1}{1-2\tau}}\). The total density vanishes quite slowly near the transition point

\[
M_0(t) \sim (1 - 2t)^{1/8} \left( \ln \frac{1}{1 - 2t} \right)^{-1/2}.
\]  

(19)

We note that the density follows a different law than the one characterizing higher than first moments \([16]\).

The size distribution does not follow a scaling behavior asymptotically and the log-normal distribution is responsible for the multiscaling behavior \([10]\) of the moments. This differs from aggregation processes where the moments diverge as \(n \to \infty\)\(, \) with the exponent \(\alpha_n\) linear in \(n\).

### C. Instant Gelation (\(\lambda > 2\))

Gelation is now instantaneous and complete, that is \(A_k(t) = 0\) for all \(k\) when \(t > 0\). To prove this assertion we assume the opposite and arrive at a contradiction. Our analysis follows van Dongen’s approach developed in the context of aggregation processes \([15]\).

The moments \(M_n\) with integer \(n \geq 2\) evolve according to \([9]\). The first term in the summation yields a lower bound for their growth rate

\[
\frac{dM_n}{dt} \geq n(n - 1)M_{n-2+\lambda} \geq n(n - 1)(M_n)^{1+\Lambda}.
\]  

(20)

with \(\Lambda = \frac{\lambda - 2}{n-1}\). The second inequality follows from the Jensen’s inequality as shown below. Consider the auxiliary functions \(M_n\), evolving according to

\[
\frac{dM_n}{dt} = n(n - 1)(M_n)^{1+\Lambda}.
\]  

(21)

Solving this equation subject to the initial condition \(M_n(0) = 1\) yields \(M_n = [1 - n(\lambda - 2)\tau]^{-1/\Lambda}\). Therefore, \(M_n \to \infty\) as \(\tau \to \tau_n = n^{-1}(\lambda - 2)^{-1}\). Since \(M_n \geq M_0\), the moment \(M_n\) diverges at least at \(\tau_n\). The series of times \(\tau_n\) set an upper bound for the gelation time \(\tau_c\) since all moments should be finite for \(\tau < \tau_c\). As \(\tau_n \to 0\) when \(n \to \infty\), we conclude that \(\tau_c = 0\) and then, the gelation time vanishes \(t_c = 0\).

The inequality \(M_{n-2+\lambda} \geq (M_n)^{1+\Lambda}\) with \(\Lambda = \frac{\lambda - 2}{n-1}\) is derived as follows. Let the parameters \(p_j \geq 0\) satisfy \(\sum_j p_j = 1\) and let \(\Phi(x)\) be a convex function. A convex function satisfies the Jensen inequality

\[
\sum_{j=1}^{\infty} p_j \Phi(x_j) \geq \Phi \left( \sum_{j=1}^{\infty} p_j x_j \right).
\]  

(22)

First, we substitute the coefficients \(p_j = jA_j\) (from mass conservation \(\sum_j jA_j = 1\)) and the convex function \(\Phi(x) = x^{1+\Lambda}\) \((\Lambda > 0\) for \(\Lambda > 2\)) into the Jensen inequality. Then, choosing \(x_j = j^{\alpha-1}\) and using \(\sum_j p_j x_j = \sum_j j^\mu A_j = M_\alpha\) and \(\sum_j p_j \Phi(x_j) = M_{n-2+\lambda}\) yields the above inequality.

### IV. GENERALIZED KERNELS

The rates \(K(i,j)\) underlying exchange processes are typically homogeneous functions of \(i\) and \(j\) (at least for large \(i\) and \(j\)). We restrict ourselves to such kernels. Apart from the homogeneity degree \(2\lambda\), homogeneous kernels are characterized by an additional exponent \(\nu\) defined through the asymptotic \(K(1,j) \sim j^{\nu}\) as \(j \to \infty\).

For \(i \ll j\) the exchange kernel scales as \(K(i,j) = i^{2\lambda} K(1,j/i) \sim i^{\nu} j^{\nu}\) with \(2\lambda = \nu + \mu\). Therefore, we consider a specific generalization of the product kernel that exhibits these homogeneity properties

\[
K(i,j) = i^{\nu} j^\mu + i^\mu j^{\nu}.
\]  

(23)

More precisely, the asymptotics \(K(i,j) \sim i^{\nu} j^\mu\) occurs for \(i \ll j\) if \(\nu \geq \mu\); since the kernel is symmetric, we can assume that \(\nu \geq \mu\) without loss of generality. We expect that the homogeneity indices govern the overall qualitative behavior (growth, gelation, instant gelation), while the precise form of the kernel controls quantitative characteristics such as the size distribution.

For this exchange kernel, the rate equations \([2]\) become

\[
\frac{dA_k}{dt} = M_\mu [(k + 1)^\nu A_{k+1} + (k - 1)^\nu A_{k-1} - 2k^\nu A_k] + M_\nu [(k + 1)^\mu A_{k+1} + (k - 1)^\mu A_{k-1} - 2k^\mu A_k].
\]

The following generalization of the modified time variable

\[
\tau = \int_0^t dt' \sqrt{M_\mu(t')M_\mu(t')}
\]  

(24)

handles the two indices symmetrically. In terms of this time, the evolution equations are

\[
\frac{dA_k}{d\tau} = R [(k + 1)^\nu A_{k+1} + (k - 1)^\nu A_{k-1} - 2k^\nu A_k] + R^{-1} [(k + 1)^\mu A_{k+1} + (k - 1)^\mu A_{k-1} - 2k^\mu A_k],
\]

with \(R = \sqrt{M_\mu/M_\nu}\). Of course, the dynamics conserve mass: \(\frac{d}{d\tau} M_1 = 0\). Higher integer moments evolve according to

\[
\frac{dM_n}{d\tau} = 2 \sum_{i=1}^{n/2} \left( \frac{n}{2i} \right) \left[ R M_{n-2i+\nu} + R^{-1} M_{n-2i+\mu} \right].
\]  

(25)

When \(\nu < 2\), the scaling analysis follows closely the product kernel case. The overall growth laws \([9]\) and \([7]\) remain unchanged and the homogeneity degree \(\lambda\) characterizes the scaling behavior. However, we shall see that the individual indices \(\nu\) and \(\mu\) play an important role since they dictate the range for which this law holds.

We seek a scaling solution of the form \([5]\). The scaling function \(\Phi(x)\) satisfies

\[
\frac{d^2}{dx^2} \left[ (Ux^\nu + Vx^\mu) \Phi(x) \right] + x \frac{d}{dx} \Phi(x) + 2\Phi(x) = 0
\]  

(26)
with the constants $U = \alpha^{-1} A$ and $V = \alpha^{-1} A^{-1}$ determined from the ratio $A = \sqrt{J_\nu/J'_\nu}$. The scaling function reads

$$\Phi(x) = C \frac{x}{U x^\nu + V x^\mu} \exp \left[ -\int_0^x dy \frac{y}{U y^\nu + V y^\mu} \right]. \quad (27)$$

The scaling solution involves three parameters $U$, $V$, and $C$. Substituting $U = \alpha^{-1} A$ and $V = \alpha^{-1} A^{-1}$ into the equality $A = \sqrt{J_\nu/J'_\nu}$ yields a closed equation for the parameter $A$. Once $A$ is determined, the parameters $U$ and $V$ follow, and finally, the amplitude $C$ is found from the normalization $J_1 = 1$.

We illustrate this procedure for the special case $(\nu, \mu) = (1, 0)$, i.e., for the pure sum kernel $K(i, j) = i + j$. In this case, the integral on the right-hand side of Eq. (27) is readily computed. Using $U = \frac{4}{2}$ and $V = \frac{3}{2}$, we arrive at

$$\Phi(x) = C x (1 + A^2 x)^{a-1} \exp \left[ -a A^2 x \right] \quad (28)$$

with $a = \frac{4}{3} A^{-3}$. We now substitute this solution into the right-hand side of the equality $A = \sqrt{J_\nu/J'_\nu}$ and transform it into the transcendental equation $(\frac{2}{3})^a \Gamma(a, a + a^{-1} = 1$ involving the incomplete gamma function (see Appendix A). The amplitude is then explicitly evaluated to give $C = a A^6$. Numerically, we find $a \approx 2.82649$, $A \approx 0.428397$, and $C \approx 0.0174713$. Interestingly, there is a nontrivial algebraic correction to the leading exponential behavior, $\Phi(x) \sim x^a \exp(-a A x)$ for large $x$.

On the boundary $\nu = 2$ separating regime III from the two other regimes, the solution of Eq. (27) significantly simplifies. We find $A = 1/[2(2 - \mu)]$, $U = 1/4$, $V = 1/(2 - \mu)^2$, and consequently, the scaling function

$$\Phi(x) = C x^{1-\mu} \left[ 1 + \frac{x^{2-\mu}}{4(2 - \mu)^2} \right]^{-1-\frac{\mu}{2}}. \quad (29)$$

The constant $C = 2 [2(2 - \mu)]^{-1-\frac{\mu}{2}} [B(\frac{1}{2-\mu}, \frac{3}{2-\mu})]^{-1}$ is expressed in terms of the beta function. Remarkably, the scaling function (29) exhibits a universal large-$x$ asymptotic behavior

$$\Phi(x) \sim x^{-5}. \quad (30)$$

In other words, the size distribution is algebraic, $A_k(\tau) \sim k^{-5} \tau^{3a}$ where $a = (2 - \lambda)^{-1} = 2/(2 - \mu)$. With this algebraic divergence, sufficiently small moments are characterized by ordinary scaling behavior while higher moments exhibit multiscaling behavior:

$$M_n \sim \begin{cases} \tau^{a(n-1)} & n < 4, \\ \tau^{a(n-1)/4} & n > 4. \end{cases} \quad (31)$$

This behavior follows from the leading term in the moment equation (25), viz. $\frac{d}{dt} M_n = n(n-1)M_{n-1}$. With $R = \sqrt{M_0/M_2} \approx A t^{-1}$ and $A = \alpha/4$, this equation becomes $\frac{d}{dt} M_n = \frac{\alpha(n-1)}{4} M_n$, leading to the multiscaling behavior (31).

The determination of $A$ in the general situation requires numerical evaluation, yet the form and nature of the size distribution is clear. For example, the minimal (maximal) index governs the distribution of small (large) clusters. Indeed, from Eq. (27), the extremal behaviors are

$$\Phi(x) \sim \begin{cases} x^{1-\mu} & x \ll 1, \\ \exp[-x^2] & x \gg 1. \end{cases} \quad (32)$$

Apart from the point $(\nu, \mu) = (2, 2)$, the scaling solution holds for all $\nu \leq 2$. As in the product kernel case, growth occurs when $\lambda < 3/2$ and gelation occurs when $3/2 < \lambda < 2$.

For $\nu > 2$, the scaling solution (27) predicts $\Phi \sim x^{1-\nu}$. Such behavior is inconsistent since the moment $J_\mu$ diverges and instead, instantaneous gelation occurs. The moments $M_n$ with $n > 1$ satisfy Eq. (25), and the first term in the summation yields a lower bound for the moment growth $\frac{d}{dt} M_n \geq R n(n-1) M_{n-2+\nu}$. Keeping only this term and absorbing the factor $R$ into the time variable, the previous proof applies. Thus, gelation is instantaneous.

To summarize, there are 3 types of behaviors, determined by the homogeneity degrees $\mu$ and $\nu$ (Fig. 1):

I Growth. The cluster size grows indefinitely, and the size distribution obeys scaling.

II Gelation. The cluster size diverges in a finite time and the size distribution follows a scaling solution near the gelation time. Gelation is complete.

III Instant Gelation. The cluster size distribution vanishes for all $t > 0$.

The cluster size distribution exhibits a scaling behavior in regimes I and II. Scaling behavior underlies the
system everywhere except for regime III and the point (2, 2). In the bulk of regimes I and II the size distribution is a stretched exponential, while in the boundary with region III, the cluster size distribution has an algebraic tail. Last, at the point $(\mu, \nu) = (2, 2)$ scaling breaks down and the distribution is log-normal.

V. THE GELATION TIME

Instantaneous gelation is certainly counter intuitive: A finite time singularity that occurs at time $t = +0!$ Instantaneous gelation was investigated exclusively in the context of aggregation [15, 16, 17, 18, 19, 20, 21]. For infinite systems, it is impossible to quantify the difference between two instant gelling. Finite systems, on the other hand, naturally quantify how fast a system gels.

Consider a system consisting initially of $N$ monomers. In a finite time $t_N$, all mass in the system condenses into a single “runaway” cluster. How does the average gelation time $T_N = (t_N)$ depend on $N$? When growth or ordinary gelation occurs, the answer follows from our previous analysis. In the scaling regime, the growth law indicates that the condensation time grows algebraically with the system size, $T_N \sim N^{1/\beta}$. In the case of ordinary gelation, the average gelation time saturates at an $N$-independent value: $T_N \rightarrow t_c$. The interesting case is instant gelation where the gelation time vanishes in the thermodynamic limit, $T_N \rightarrow 0$ as $N \rightarrow \infty$.

For simplicity, we discuss the product kernel. The vanishing gelation time is ultimately related to the short time behavior. Early on, loss terms in the rate equation are negligible and to leading order $\frac{d}{dt} A_j \equiv (j+1)^\lambda A_{j+1}$, where we tacitly assumed $\tau \equiv t$. For the initial condition $A_j(0) = \delta_{j,1}$, the leading order behavior of the density is

$$A_{j+1} \approx (j!)^{\lambda-1} t^j.$$  \hspace{1cm} (33)

In a finite system consisting initially of $N$ monomers, a $j$-mer first appears at time $t_j \approx (j!)^{-(\lambda-1)/j} N^{-1/j}$, estimated from $NA_j(t_j) = 1$. For example, the first dimer and trimer appear at times $t_2 = N^{-1}$ and $t_3 = 2^{-(\lambda-1)/2} N^{-1/2}$, respectively. By definition, the times increase monotonically, $t_{j+1} > t_j$, yet the above estimates increase monotonically only for sufficiently small $j < j_*$. From $t_{j_*} = t_{j_*+1}$, we obtain the extremum $j_* = (\lambda - 1)^{-1} \ln N$ using the Stirling formula. The corresponding time $T_* \equiv t_{j_*}$ is

$$T_* \sim \left(\frac{\lambda - 1}{\ln N}\right)^{\lambda-1}. \hspace{1cm} (34)$$

For later times, $t \gg T_*$, the rate equations should be modified to account for the finiteness of the system (see e.g. [22, 23]) since significant statistical fluctuations are induced by large runaway clusters that take over (eventually only one such cluster remains). The critical size of such clusters is $j_* \sim (\lambda - 1)^{-1} \ln N$. As a complete analytical solution seems out of reach, we proceed heuristically by focusing on the leading cluster that eventually grows to be the gel. Since it exchanges monomers back and forth with other clusters its growth mechanism is diffusive. For an ordinary diffusive process, $\frac{d}{dt} \langle k \rangle = 0$, while $\frac{d}{dt} \langle k^2 \rangle = D$. In our case, $D = k^\lambda$ with the typical size $k^2 \equiv \langle k^2 \rangle$. Therefore, the typical size of the runaway cluster grows according to

$$\frac{dk}{dt} = k^{\lambda-1}. \hspace{1cm} (35)$$

Integrating this rate equation from the critical size $k = j_*$ to the system size $k = N$ gives the gelation time

$$T_N = T_* + \frac{1}{\lambda - 2} \left[ \frac{1}{j_*^{\lambda-2}} - \frac{1}{N^{\lambda-2}} \right]. \hspace{1cm} (36)$$

Since $j_* = (\lambda - 1)^{-1} \ln N$, the duration of the latter growth phase is much larger than that of the nucleation phase, $T_N \gg T_*$. Therefore, the gelation time vanishes logarithmically

$$T_N \sim (\ln N)^{-(\lambda-2)}, \hspace{1cm} (37)$$

in the thermodynamic limit. A straightforward extension of the above argument to the generalized exchange kernel gives $T_N \sim (\ln N)^{-(\nu-2)}$.

Therefore, in a finite system it may be difficult to distinguish instantaneous gelation from the ordinary one. We verified the logarithmic law numerically for $\lambda = 3$ (Fig. 2). Probing fluctuations in the gelation time, we observe that the normalized variance $\sigma_N^2 = \langle t_N^2 \rangle / \langle t_N \rangle^2 - 1$ vanishes logarithmically in the thermodynamic limit (Fig. 2). The distribution of normalized
gelation times becomes trivial \( P(t_N/T_N) \rightarrow \delta(z - 1) \) implying that the gelation time is a self-averaging quantity.

We also examined the gelation time in two other growth processes, namely aggregation \([10, 11, 12]\) and addition \([24, 25]\). The above heuristic picture yields a similar logarithmic law albeit with a different exponent \([21]\). Self-averaging is observed numerically as well, and we conclude that the behavior found for exchange processes is generic.

VI. APPLICATIONS TO COARSENING

In exchange processes, a monomer detaches from a cluster and subsequently re-attaches to another cluster. This elementary mechanism underlies a number of growth and coarsening processes. We apply our general theory to two coarsening processes.

A. Infinite range Ising-Kawasaki model

The zero temperature Ising model with infinite range Kawasaki dynamics evolves via exchanges of spins of opposite signs belonging to domain walls \([24, 25]\). This model is equivalent to the Shelling’s segregation model \([\mathbb{R}]\). In the limit of a vanishing volume fraction of one of the two phases, the domains of the minority phase are isolated and the process is essentially an exchange process with a product kernel \( K(i, j) = (ij)^\lambda \). The dependence of the number of exchange candidates (i.e., spins in domain walls that can lower their energy by hoping to a different cluster) on the cluster size dictates the homogeneity degree. For spherical clusters, only perimeter spins may exchange. Since the island size and the surface size grow with the radius according to \( k \sim R^d \) and \( \sigma \sim R^{d-1} \sim k^{(d-1)/d} \), respectively, one has \( \lambda = (d - 1)/d \) and \( \beta = 1/(3 - 2\lambda) = d/(d + 2) \). The dynamical exponent (defined through \( R \sim t^z \)) is therefore \( z = 1/(d + 2) \). If the islands are polygons, a distinct possibility on a lattice, then only corner spins are active so \( \lambda = 0 \), and consequently \( \beta = 1/3 \) and \( z = 1/(3d) \). Both estimates agree in one dimension, consistent with the exact solution \( z = 1/3 \) \([20]\).

B. Coarsening of thin granular layers

In electrostatically driven granular layers, clusters nucleate around large grains \([30]\). Then, as charged grains oscillate back and forth between the bounding plates due to the oscillating electric field, they may scatter off the plate or collide with other particles. Consequently, individual grains may transfer from one cluster to another. The rate of hoping into and out of a cluster is proportional to its area. Therefore, the homogeneity degree is unity, \( \lambda = 1 \), implying \( \beta = 1 \) and a dynamical exponent of \( z = 1/d \). In two dimensions, this prediction is consistent with the experimental observations \( z = 1/2 \) \([30]\). The corresponding size distribution \( \Phi(x) = e^{-x} \) provides a reasonable approximation for the experimental size distribution, obtained from a relatively small number of clusters (see Fig. 3). The normalized variance, defined via \( \sigma^2 = J_2/J_1^2 - 1 \), is experimentally found to be \( \sigma = 0.80 \pm 0.05 \) compared with the theoretical value \( \sigma = 1 \). Comparing "spatial" exchange processes where grains are exchanged only between neighboring clusters with further experimental data may help elucidate the relevance of spatial correlations.

VII. CONCLUSIONS

We have shown that kinetics of exchange processes are classified by the homogeneity indices of the governing rates. There are three possible regimes including indefinite growth, gelation in a finite time, and instant gelation. Scaling behavior underlies the first two regimes. The size distributions are generally extended, decaying exponentially or algebraically for large sizes, in contrast with migration processes.

We also studied the gelation time in finite systems and found that it decays rather slowly, following an inverse logarithmic law. It would be interesting to determine the full time dependent behavior of moments of the size distribution in the instant gelation regime. In the realm of aggregation, instantaneous gelation is relevant in astrophysics, e.g., to the coalescence of planetesimals to
form planets or of stars to form super-massive black holes (see [21] and references therein). The physical relevance of instant gelation in exchange processes has yet to be demonstrated.

Our description was on a mean-field level where all pairs of clusters in the system are equally likely to interact. It will be interesting to incorporate spatial fluctuations into this description. The nature of the spatial fluctuations depends on the mechanism for transporting monomers from one cluster to the other. For diffusive transport, one can incorporate effective fluxes into clusters, using the standard techniques developed for reaction-diffusion processes.

Acknowledgments

We thank Igor Aronson and Avner Peleg for useful discussions. We are grateful to Igor Aronson for providing the experimental data. This research was supported by DOE (W-7405-ENG-36).

APPENDIX A: THE CASE $({\nu, \mu}) = (1, 0)$

Substituting Eq. (28) into $A^2 = J_0/J_1$ yields

$$1 = \frac{\int_0^\infty dx x^2 (1 + x)^{-b-1} e^{-ax}}{\int_0^\infty dx x (1 + x)^{b-1} e^{-ax}}$$

with $b = a$. Evaluation of the ratio of the integrals is performed as follows

$$1 = \frac{-d}{da} \ln \left[ \int_0^\infty dx x (1 + x)^{b-1} e^{-ax} \right] \bigg|_{a=b}$$

$$= \frac{-d}{da} \ln \left[ \frac{\int_0^\infty dx (1 + x)^{b-1} e^{-ax}}{\int_0^\infty dx x (1 + x)^{b-1} e^{-ax}} \right] \bigg|_{a=b}$$

$$= \frac{-d}{da} \ln \left[ \frac{(e^a a^{-b} \Gamma(b, a))}{a^{-1}} \right] \bigg|_{a=b}$$

$$= a^{-2} + e^a a^{-a-1} \Gamma(a, a).$$
