It is well known that energy fluxes will produce gravitational wave memory. The gravitational wave memory produced by background including cosmic microwave background (CMB), cosmic neutrino background (CνB), and gravitational wave background is investigated in this work. We construct a theory relating the gravitational wave memory strength to the energy flux of a stochastic background. We find that the resulted gravitational wave memory behaves as a constantly varying metric tensor. Such a varying metric tensor will introduce a quadrupole structure to the universe expansion. The gravitational wave memory due to the CMB is too small to be detected. But the gravitational wave memory due to the CνB and the gravitational wave background is marginally detectable. Interestingly, such detection can be used to estimate the neutrino masses and the properties of the gravitational wave background.

Introduction.— Gravitational wave (GW) memory is an outstanding prediction of general relativity. Such memory was firstly realized in [1–4]. The aforementioned memory is produced directly by the gravitational wave source and is consequently called linear memory. Later, Christodoulou [5, 6] found that gravitational wave itself can also produce memory. It means the source produces gravitational wave first and the wave produces memory then. Consequently such memory is called non-linear memory. Afterward many works have been paid to the non-linear memory of compact binary objects coalescence [7–10]. The GW memory of compact binary objects coalescence may be observed in the near future [11–14]. Recently people found that the non-linear memory is related to the soft theorem [15–24]. The infrared triangle makes the GW memory highly interesting to the fundamental physics [21–24].

In addition to GW, other radiations carrying energy fluxes can also produce GW memory [15, 20, 22]. The GW memory produced by gamma ray [26–30] and by neutrino emission [31, 32] has been investigated. And more, works about GW memory within the alternative gravity theory than general relativity have been done [24, 33–34]. But all of the existing works on GW memory are about isolated sources. Since it has been shown that the passage of any kind of matter or radiation will cause GW memory [15, 20], it is valuable to study the GW memory produced by stochastic background radiation which can interweave fundamental physics, cosmology, and astrophysics. At the same time, such GW memory may provide a brand new means to detect GW memory which has not been detected yet. This new mean circumvents the low frequency difficulty which is related to the quasi-direct behavior of GW memory [14]. Unfortunately there is no study on the GW memory produced by stochastic background radiation till now. That is the topic of the current work. We construct a theory to describe the GW memory produced by the energy flux of cosmic radiation. Our theory predicts that the observed universe expansion admits a quadrupole structure due to such GW memory. To the best of our knowledge, this is the first work on the gravitational wave memory due to cosmic background radiation.

The most well known cosmic background radiation is the cosmic microwave background (CMB) which has been well detected [35–38]. It is interesting to ask how about the GW memory produced by CMB. Is it possible to detect the related GW memory? The cosmic neutrino background (CνB) should exist [39, 40] based on the prediction of the standard cosmological model but has not been detected yet [11]. It is also quite interesting to ask whether it is possible to use the related GW memory of CνB to detect or constrain the property of neutrino. Other than CMB and CνB, the stochastic background of GW (SGWB) should also exist [42] but has not been detected too [43, 44]. It is valuable to relate the stochastic background of GW to the GW memory and use the GW memory to estimate or constraint the strength of the stochastic background of GW.

We find that the gravitational wave memory due to the CMB is too small to be detected, but the ones due to the CνB and the SGWB may be marginally detectable. Throughout this paper we will use units c = G = 1.

Theory of gravitational wave memory due to cosmic background radiation.— It is well known that the GW memory produced by GW itself can be expressed as [2, 4, 10, 45]

\[
\int_t^\infty dt' \left[ \int \frac{d^3 p_{GW}^*}{d^3 p_{GW} d^3 k} \frac{n_i n_j}{1 - n \cdot N} \delta^3 \mathbf{r} \right]^{TT},
\]

(1)
Harmonic bases related to the energy flux with spin weighted -2 spherical tances. Consequently, we can express the associated GW memory using the mathematical tricks introduced in [45–47]. We have used $R$ to denote the comoving distance. Consequently, a $R$ is the area radius of the wave front passing the observer. 

Background radiation behavior on a slice of constant cos-elliptical pattern of Universe expansion shown in the center) is produced by the sources from all directions relative to the source. The GW memory (the proper time. We have used $F$ ing to the vertical axis is the conformal time instead of the $dE/dt^\omega$ is the luminosity distance between the observer and the source. The time $\bar{t}$ is the energy flux radiated from the source and $\rho$ is the angular integration, we express the di-recton $\bar{t}$ corresponding to a cosmic background radiation, there are

$$\sum_{l=2}^{\infty} \sum_{m=-l}^{l} h_{lm}^{-1}[-Y_{lm}],$$

$$h_{lm}^{-1} = \frac{32\pi}{D_L} \sqrt{\frac{(l-2)!}{(l+2)!}} \int_{-\infty}^{\infty} t^2(t') F^\omega d|Y_{lm}|dY', l \geq 2,$$

where the overline means the complex conjugate and $Y_{lm}$ is the usual spherical harmonic function (spin weight 0). The $l \geq 2$ modes on the right hand side of the above equation are related to the anisotropy of the radiation. The spacetime curvature of the Friedmann-Lemaître-Robertson-Walker metric will enhance the GW memory by a red shift factor $1 + a(t_0)$ [50, 51, 52]. Such enhancement is also true for non-memory GW [51, 52]. If we use $R$ to denote the comoving distance Eq. (3) becomes

$$h_{lm}^{-1} = 32\pi R \sqrt{\frac{(l-2)!}{(l+2)!}} \int_{-\infty}^{t} t^2(t') F^\omega d|Y_{lm}|dY', l \geq 2,$$

where the gauge choice of the universe scale factor $a(t_0) = 1$ corresponding to current observation has been chosen as usual. We emphasize that $R$ in this equation is the comoving distance instead of the luminosity distance. According to the soft theorem [15–20], the energy flux $F^\omega$ involved in the above equation can be contributed by gravitational wave, electromagnetic wave, neutrino, and any other radiations [19, 20, 25–32]. We illustrate the physical picture of the GW memory due to the cosmic background radiation in Fig. 1.

In the observer frame, the GW memory produced by the radiation from direction $(\theta, \phi)$ is

$$h_{ij}^{-1}(\theta, \phi) = \sum_{l=2}^{\infty} \sum_{m=-l}^{l} \{ \Re[h_{lm}^{-1} - Y_{lm}(\pi - \theta, 2\pi - \phi)] e_i^j(\pi - \theta, 2\pi - \phi) - \Im[h_{lm}^{-1} - Y_{lm}(\pi - \theta, 2\pi - \phi)] e_i^j(\pi - \theta, 2\pi - \phi) \},$$

where $e_i^j$ are the polarization tensors of the GW. Corresponding to a cosmic background radiation, there are similar sources in all directions. We sum all directions together

$$h_{ij}^{-1} = \int h_{ij}^{-1}(\theta, \phi) d\Omega.$$  

(7)

Straightforwardly we have

$$h_{ij}^{-1} = \int h_{ij}^{-1}(\theta, \phi) d\Omega,$$

(8)

$$\dot{h}_{ij}^{-1}(\theta, \phi) = \sum_{l=2}^{\infty} \sum_{m=-l}^{l} \{ \Re[h_{lm}^{-1} - Y_{lm}(\pi - \theta, 2\pi - \phi)] e_i^j(\pi - \theta, 2\pi - \phi) - \Im[h_{lm}^{-1} - Y_{lm}(\pi - \theta, 2\pi - \phi)] e_i^j(\pi - \theta, 2\pi - \phi) \},$$

(9)

$$\dot{h}_{lm}^{-1} = 32\pi R \sqrt{\frac{(l-2)!}{(l+2)!}} \int F^\omega |Y_{lm}|dY', l \geq 2,$$

(10)

where $a(t_0) = 1$ has been used for the current cosmological time.

Regarding the angular integration, we express the di-rection dependence of the radiation as

$$F^\omega = F_0 \rho(\theta', \phi'),$$

(11)

$$\int \rho(\theta', \phi') dY' = 1.$$  

(12)

Then Eq. (10) becomes

$$\dot{h}_{lm}^{-1} = 32\pi F_0 R \sqrt{\frac{(l-2)!}{(l+2)!}} a_{lm}, l \geq 2.$$  

(13)
Gravitational wave memory due to CMB. — According to the Stephan-Boltzmann law, the radiation flux of CMB is about $F_0 \approx 10^{-42} \text{s}^{-2}$ [54]. Since the photons decouple from the baryons at about $10^3$ years after big bang, we can estimate that the CMB source is about $R \sim 10^{17}\text{s}$ away from us. The anisotropy modes $a_{2m}$ of CMB are about $10^{-5}$ [35, 38]. According to (17), the strength of the gravitational wave memory due to CMB is about

$$\dot{h}_{ij}^{\text{CMB}} \approx 10^{-35}\text{s}^{-1}. \quad (25)$$

Compared to the cosmic expansion rate $10^{-17}\text{s}^{-1}$ the above correction is too tiny to be detected.

Gravitational wave memory due to CνB. — The massive neutrinos of the CνB are fundamental ingredients of the radiation-dominated early universe and are important non-relativistic probes of the large-scale structure formation in the late universe. We expect that the relic neutrinos have become non-relativistic at present. So the CνB abundance $\Omega_{\nu}$ today can be related to the sum of masses as [54]

$$\Omega_{\nu} = \frac{1}{h^2} \sum_i m_{\nu_i}, \quad (26)$$

where $h \approx 0.7$ is the reduced Hubble constant. The sum of the neutrino masses has been previously restricted to the approximate range $0.06\text{eV} \lesssim \sum_i m_{\nu_i} \lesssim 6\text{eV}$ [54]. In the following, we find that the detection of the quadrupole structure of the Universe expansion, which represents the GW memory produced by cosmic background radiation, can be used as a new probe to constrain the sum of the neutrino masses.

The flux of CνB can be estimated as

$$F_0 = \frac{3H_0^2}{8\pi} \Omega_{\nu}, \quad (27)$$

where $H_0$ means the Hubble constant. Since the neutrinos decouple from the baryons at about one second after the big bang, we can estimate that CνB source is about $R \sim 10^{17}\text{s}$ away from us. Till now there is no detail knowledge about the anisotropy of CνB, but even if the anisotropy is small before the neutrino becomes non-relativistic, the finite mass of neutrinos amplifies the anisotropy in the low multipole moments after the non-relativistic transition. The anisotropies for a neutrino mass of $0.01\text{eV}$ are amplified by more than $100$ times compared to the massless case [54]. If we assume that the anisotropy of CνB takes a value $1$ for estimation, the resulting strength of the gravitational wave memory due to CνB is about

$$\dot{h}_{ij}^{\text{MCB}} \approx \Omega_{\nu} \times 10^{-18}\text{s}^{-1}. \quad (28)$$

Combining Eqs. (26) and (28), we can use the detection of the quadrupole structure of the Universe expansion to constrain the sum of neutrino masses. Denoting the
Gravitational wave memory due to SGWB.—There are many types of SGWB. Here we discuss the relic one and the one associated with CBC as examples. Standard inflation theory predicts that the relic SGWB admits strength $\rho_{GW} \approx 10^{-15}$ above frequency $10^{-17} \text{Hz}$ [42]. This prediction results in $F_0 \approx 10^{-50} \text{s}^{-2}$. Since the relic SGWB is produced by inflation [54, 57], the comoving distance of SGWB sources is about $R \sim 10^{17} \text{s}$. Consequently, the strength of the gravitational wave memory due to relic SGWB is at most $10^{-33} \text{s}^{-1}$ even the anisotropy takes the largest value 10 (Each of the 9 independent bases contributes one). Although this strength is three orders larger than that of GW memory due to CMB, it is still too tiny to be detected compared to the cosmic expansion rate $10^{-17} \text{s}^{-1}$.

Deviating from standard inflation theory, the relic SGWB may be much stronger than the one mentioned above. The combination of the latest Planck observations of CMB and leusing on baryon acoustic oscillations (BAO) and big bang nucleosynthesis (BBN) measurements can be used to determine $F_0 < 3.8 \times 10^6 \times 2h^2 \text{eV} \sim 10^{-42} \text{s}^{-2}$ [55, 59]. If the anisotropy of the relic SGWB can be as high as $10^{-1}$ [60], the strength of the gravitational wave memory due to relic SGWB can reach about

$$\tilde{h}^{\text{relicSGWB}}_{ij} \lesssim 10^{-23} \text{s}^{-1}.$$ (30)

The strength of SGWB from compact binary coalescence (CBC) can be expressed as

$$\Omega_{GW}(f) = A_{\text{ref}} \left( \frac{f}{f_{\text{ref}}} \right)^{9/2},$$ (31)

which reduces to

$$F_0 = \frac{9H_0^2}{16\pi} A_{\text{ref}} (f_{\text{merg}}^{\uparrow} - f_{\text{form}}^{\uparrow}).$$ (32)

Here $f_{\text{merg}}$ and $f_{\text{form}}$ correspond to the GW frequency when the CBC merges and forms respectively. In addition, $f_{\text{ref}}$ and $A_{\text{ref}}$ are the reference frequency and the corresponding SGWB strength which can be determined by observation. Since $f_{\text{merg}} \gg f_{\text{form}}$ we have

$$F_0 \approx \frac{9H_0^2}{16\pi} A_{\text{ref}} \left( \frac{f_{\text{merg}}}{f_{\text{ref}}} \right)^{9/2}.$$ (33)

Regarding the stellar massive CBC which admits $f_{\text{merg}} \approx 10^{13} \text{Hz}$, ground based detectors have constrained $A_{\text{ref}} < 10^{-3} \text{ at } f_{\text{ref}} = 25 \text{Hz}$ [13]. This constraint reduces to $F_0 \lesssim 10^{-44} \text{s}^{-2}$. About the super-massive CBC which admits $f_{\text{merg}} \approx 10^{-3} \text{Hz}$, pulsar timing array (PTA) has constrained $A_{\text{ref}} < 10^{-5} \text{ at } f_{\text{ref}} = 10^{-3} \text{Hz}$ [61]. This constraint reduces to $F_0 \lesssim 10^{-39} \text{s}^{-2}$.

CBCs are located at different distances. If the distribution is independent of distance, the sources with larger distances dominate the GW memory contribution according to Eq. (31). We have known that galaxies have formed at least 10 billion years ago [62]. So we can estimate that $R \sim 10^{17} \text{s}$ for CBC. Like the relic SGWB, if the anisotropy of the CBC SGWB can be as high as $10^{-1}$, the strength of the gravitational wave memory due to the stellar massive CBC and the super-massive CBC SGWB may reach respectively about

$$\tilde{h}^{\text{superCBCSGWB}}_{ij} \approx 10^{-28} \text{s}^{-1},$$ (34)

$$\tilde{h}^{\text{superCBCSGWB}}_{ij} \approx 10^{-23} \text{s}^{-1}.$$ (35)

Gravitational wave memory due to the GW foreground of binary white dwarfs.—The GW foreground of binary white dwarfs depends strongly on the Galactic-binary merger rate and on their characteristic chirp masses, but only weakly on other parameters [63].

$$S_h(f) \approx 1.9 \times 10^{-44}(f/\text{Hz})^{-7/3} \text{Hz}^{-1}$$ (36)

$$\times \left( \frac{D_{\text{char}}}{6.4 \text{kpc}} \right)^{-2} \left( \frac{R_{\text{gal}}}{0.015 \text{yr}} \right) \left( \frac{M_{\text{char}}}{0.35 M_\odot} \right)^{5/3},$$

where $D_{\text{char}}$ is the characteristic distance from Earth to Galactic binaries; $R_{\text{gal}}$ is the binary merger rate in the Galaxy; and $M_{\text{char}}$ is the characteristic chirp mass. If we let these parameters take the expected values, we have

$$F_0 \approx 4.5 \times 10^{-44} \times (f_{\uparrow}^{\text{up}} - f_{\uparrow}^{\text{low}}),$$ (37)

where $f_{\text{up}}$ and $f_{\text{low}}$ are the frequency range of the foreground. At most $f_{\uparrow}^{\text{up}} - f_{\uparrow}^{\text{low}} \approx 1$ [64]. In addition, we can use the size of our galaxy to estimate $R \sim 10^{11} \text{s}$. The anisotropy of the foreground is at most $10^{-1}$, so the strength of the gravitational wave memory due to the foreground must be less than

$$\tilde{h}^{\text{GWBGW}}_{ij} \lesssim 10^{-34} \text{s}^{-1}.$$ (38)

It is too tiny to be detected.

Quadrupole structure of the Universe expansion.—The above analysis indicates that the gravitational wave memory due to cosmic background radiation introduces a quadrupole structure to the Universe expansion. Current observations suggest that this quadrupole should be less than $I \sim 10^{-18} \text{s}^{-1}$ [65]. Plugging this constrain in Eq. (29) we get

$$\sum_i m_{\nu_i} \lesssim 46 \text{eV}.$$ (39)

This constraint is consistent with previous findings [54]. The data of the Hubble telescope and the GAIA telescope may tighten this constraint by one or two orders
Interesting scientific discoveries about gravitational wave memory due to cosmic background radiation may be found when the detection accuracy increases in the future.

Discussion.— For the first time, we investigated the GW memory produced by cosmic background radiation. A theory relating GW memory to the energy flux of the cosmic background radiation is constructed based on standard general relativity. According to our theory, such GW memory behaves as a quadrupole structure of the universe expansion. So the universe expansion related measurement can be used to detect this kind of GW memory. Not like interferometer type detectors, this kind of detection can circumvent the low frequency difficulty in the GW memory detection.

Before our work, there are less motivations to measure the quadrupole structure of the expanding universe within the standard ΛCDM cosmology. The current measurement accuracy is about \( I \sim 10^{-18} \text{s}^{-1} \) which is almost the same level of Hubble constant itself. Significant improvements can be achieved by using the data of the Hubble telescope, the GAIA telescope, the LAMOST telescope and their combinations.

The gravitational wave memory due to the CMB is just \( 10^{-35} \text{s}^{-1} \) which is too small to be detected. But the current knowledge permits that the gravitational wave memory due to the cosmic neutrino background and the gravitational wave background can be as strong as \( 10^{-20} \text{s}^{-1} \) and \( 10^{-23} \text{s}^{-1} \) respectively. They are marginally detectable according to the current measurement accuracy of the quadrupole structure of the universe expansion. Our work sets an important motivation to combine the data of the Hubble telescope, the GAIA telescope, the LAMOST telescope and others to measure the quadrupole structure of the universe expansion. Such measurement will not only provide direct detection of GW memory but also give important information on neutrino masses and super-massive CBC distributions.
