Vanadium dioxide (VO₂) is a much-discussed material for oxide electronics and neuromorphic computing applications. Here, heteroepitaxy of VO₂ is realized on top of oxide nanosheets that cover either the amorphous silicon dioxide surfaces of Si substrates or X-ray transparent silicon nitride membranes. The out-of-plane orientation of the VO₂ thin films is controlled at will between (011)M₁/(110)R and (−402)M₁/(002)R by coating the bulk substrates with Ti₈₀.₇O₂ and NbWO₆ nanosheets, respectively, prior to VO₂ growth. Temperature-dependent X-ray diffraction and automated crystal orientation mapping in microprobe transmission electron microscope mode (ACOM-TEM) characterize the high phase purity, the crystallographic and orientational properties of the VO₂ films. Transport measurements and soft X-ray absorption in transmission are used to probe the VO₂ metal–insulator transition, showing results of a quality equal to those from epitaxial films on bulk single-crystal substrates. Successful local manipulation of two different VO₂ orientations on a single substrate is demonstrated using VO₂ grown on lithographically patterned lines of Ti₈₀.₇O₂ and NbWO₆ nanosheets investigated by electron backscatter diffraction. Finally, the excellent suitability of these nanosheet-templated VO₂ films for advanced lensless imaging of the metal–insulator transition using coherent soft X-rays is discussed.
1. Introduction

Vanadium dioxide (VO₂) has been drawing attention since the discovery of its metal–insulator transition (MIT), signaled by a several orders of magnitude resistivity change close to 340 K. Given these remarkable properties, it may not be a surprise that VO₂ is a leading candidate material for the development of oxide devices for both low power electronics (high off-resistance), either in a more conventional field effect type of device or alternatively, neuromorphic electronic architectures as a memristive material. It has been known that the MIT occurs alongside an abrupt, first-order structural phase transformation from a metallic, tetragonal rutile (R) phase (P4_2/mmm) to an insulating, monoclinic (M1) phase (P2_1/c). Recent work points out that this transition is preceded by a purely electronic softening of Coulomb correlations within the V–V singlet dimers that characterize the insulating state, setting the energy scale for driving the near-room-temperature insulator–metal transition in this paradigm complex, correlated oxide.

Up to now, most studies of epitaxial VO₂ thin films have used Al₂O₃ and TiO₂ single crystal substrates to control film orientation, bringing along challenges of cost, limited size, and incompatibility with the current Si-based technology for future VO₂-based devices. Direct deposition of VO₂ on glass or Si substrates with a native amorphous silicon dioxide layer leads to a polycrystalline film with predominant (011)M1 orientation, whereas VO₂ is favorably grown (010)M1-oriented when a buffer layer of Pt(111) is used on a Si substrate. Epitaxial growth of VO₂ with (010)M1 orientation is possible on epitaxial layers of yttria-stabilized zirconia—YSZ(001)—on Si(001). Ideally, one would wish for direct control over VO₂ film orientation on Si or even on arbitrary substrates at will, without any concessions being made on the VO₂ film quality. Oriented growth is not only an important enabler for the fundamental study of the mechanism of the VO₂ MIT but also for potential applications for next-generation transistors, memory metamaterials, sensors, and novel hydrogen storage technology. Recently, various metal oxide films have been successfully grown on glass and Si substrates using epitaxy on the so-called oxide nanosheets. Oxide nanosheets are essentially 2D single crystals with a thickness of a few nanometers or less, and lateral size in the micrometer range. They can be made spanning a wide range of crystal lattices and 2D structural symmetries allowing for new possibilities to tailor the important structural parameters and properties of thin films on arbitrary—and thus also technologically relevant—bulk substrates. Successful implementation of nanosheets in fact means that the choice of the bulk substrate becomes a free parameter that can enter the engineering cycle of each individual application.

In the following, the reasoning and data that led to this conclusion are gone through in a step-by-step manner. A closer examination of Figure 1 shows that—considering the oxygen sub-lattices as the dominating structural entities driving potential epitaxy between the VO₂ and the nanosheets—the two distinct O–O distances of 2.90 and 2.84 Å for the VO₂ (011)M1 plane are close to the O–O distance of 2.97 Å for the TO nanosheet in the b-direction. In the a-direction, there are also two distinct O–O distances for the VO₂ (011)M1 plane, i.e., 3.38 and 4.51 Å, respectively, which are very different from the O–O distance of 3.82 Å for TO nanosheets. Highly relevant in this regard is the concept of domain matching epitaxy, which can be seen as a generalization of the more common lattice match epitaxy. In domain matching epitaxy, integral multiples of lattice planes match across the film–substrate interface, with the size of the domain (equaling integral multiples of planar spacing), determined by the degree of mismatch. This can yield epitaxy when mismatches exceed the usual 7–8% limit for regular lattice epitaxy.

2. Results and Discussion

Figure 1 shows a plan view of the TO and NWO nanosheet planes in panels (a) and (d), respectively. For the TO(NWO) nanosheets, the relevant 2D unit cell is highlighted in green (pink). In panels (b) and (c), the relevant VO₂ planes are shown for the M1 and R structures with the 2D unit cell of the TO nanosheets superimposed. Likewise, in panels (e) and (f) the 2D unit cell of the NWO nanosheets is superimposed on the relevant planes in the M1 and R VO₂ phases. What these figures show, backed up by the data of Table 1, is that the (011)M1 [(110)R] and (−402)M1 [(002)R] out-of-plane orientations of M1[R] VO₂ are compatible with the TO and NWO nanosheet symmetry and lattice constants, respectively.
(011)$_{M1}$ film can be stabilized by TO nanosheets at room temperature. At the growth temperature of 520 °C, it is the rutile phase of VO$_2$ that is being formed, and analogous considerations show that as the (110)$_R$ plane is very closely related to the room temperature (011)$_{M1}$ plane of VO$_2$ a similar domain epitaxial relationship will be at work.

In addition to the domain epitaxy ideas, we also point out that as the nanosheets are exfoliated layered materials without chemically active dangling bonds, there are only isotropic Coulomb and/or Van der Waals interactions between the growing film and the nanosheet surface. Consequently, lateral adatom–adatom interactions are significant drivers of the energetics of the early stages of (epitaxial) growth, thus helping to favor epitaxial growth also in the presence of relatively large lattice mismatch. In this manner, retention of epitaxy with lattice mismatch as high as 13% have been reported, supporting the ability of TO nanosheets to successfully template the (110)$_R$ growth of the rutile phase of VO$_2$.

We now turn to the NWO nanosheets. In this case, epitaxial growth of (−402)$_{M1}$ or (002)$_R$ VO$_2$ films are expected via straightforward lattice matching considerations. The 2D atomic structure of the (−402)$_{M1}$ plane is distorted away from a square planar symmetry (by 3° off the right angle). The lattice mismatch between this plane and the nanosheets is 3.6% and 7.9% in the $a$- and $b$-directions, respectively, which—especially given the arguments above as regards the nondirectional nature of the adatom-nanosheet interactions—we would expect to support epitaxial growth with the VO$_2$ film oriented in the (−402)$_{M1}$ direction at room temperature. For the NWO case, the high-T situation is simpler still, as the lattice mismatch between the high temperature (002)$_R$ plane and the NWO nanosheet is only 3.2%, with the same 2D square atomic structure present in both cases.

To summarize this section: detailed consideration of the oxygen sub-lattice-driven epitaxial relationships shows that for TO nanosheets, a combination of domain matching epitaxy and the weak adatom–nanosheet interactions should enable epitaxial growth of VO$_2$, with the out-of-plane orientation being (011)$_{M1}$ and (110)$_R$ at room temperature and elevated temperature, respectively. For the NWO nanosheets, the VO$_2$ orientation is expected to be (−402)$_{M1}$ and (002)$_R$.

Turning to the first step of the nanosheet-templated film growth process in practice, Figure 2 shows atomic force microscopy (AFM) images of the morphology of the bare-nanosheets of TO and NWO in panels (a) and (b). It is clear that monolayers of TO and NWO nanosheets can be fabricated on Si substrates successfully with a surface coverage exceeding 95%. The lateral size of the individual nanosheets is 3–5 µm for both TO and NWO, which is partly governed by the grain size of the parent layered crystals obtained by solid state reaction. The exfoliated nanosheets were deposited using a LB-method to form a monolayer film on Si substrates and on Si$_3$N$_4$ membranes.

Using these nanosheet layers on Si$_3$N$_4$ TEM grids as substrates, thin films of VO$_2$ were grown using PLD. In order
to determine the homogeneity and epitaxial quality of the VO₂ films with nm lateral spatial precision, orientation maps were recorded using TEM, the results of which are shown in Figure 2c–f. The data were measured in the rutile VO₂ phase at a temperature of 423 K. For the TO-templated system, a remarkably homogeneous (110)R orientation of the VO₂ film results (Figure 2c), and apart from a very few rogue patches, Figure 2d shows that the NWO nanosheets perform just as well, generating (002)R VO₂. These results are confirmed in the pole figures for these two rutile orientations shown in panels (e and f). With this nanoscopic confirmation of the excellent epitaxial growth on each individual nanosheet, the next step is a more global measure of the VO₂ structure, in both the rutile and monoclinic phases using X-ray diffraction (XRD).

Figure 3 presents the XRD data measured below and above T_{MIT} of VO₂ films grown using PLD at 520 °C on monolayers of TO (panel a) and NWO nanosheets (panel b) on Si substrates. At 303 K, the peaks seen at 2θ values of 27.90° and 57.72° in Figure 3a are from the (011)_{MIT} and (022)_{MIT} VO₂ reflections, respectively. In Figure 3b, the peak at 65.07° corresponds to the (−402)_{MIT} VO₂ reflection. At 403 K—above the MIT—above the MIT —peaks measured at 27.70°, 57.27° and 65.28° now correspond to the (110)_{R}, (220)_{R}, and (002)_{R} Bragg peaks of rutile VO₂, respectively. These XRD data confirm the excellent orientational integrity of the VO₂ films at the macroscopic scale, confirming what was seen in the TEM data. This points toward the major role of the oxygen framework in the determination of the epitaxial relationships between both nanosheet systems and the VO₂ overlayer, as discussed earlier.

One of the motivations for choosing VO₂ for this study was its dual role as a model system for both understanding strongly correlated MIT, as well as its tunable/switchable large resistance change near room temperature. Consequently, the transport behavior of VO₂ grown using PLD on nanosheets templates is of great interest, and these data are shown in Figure 4. Defining the midpoint of the transition in the resistance curve measured upon heating as the phase transition temperature, T_{MIT}, our data show transition temperatures close to the canonical value of 341 K for bulk VO₂ single crystals. The T_{MIT} of the films with out-of-plane (110)R texture (rutile c-axis in-plane) grown on TO nanosheets was 347 K, whereas for the out-of-plane (002)R textured film on NWO nanosheets T_{MIT} was 332 K. These values are in agreement with what has been found in the literature on the orientation dependence of T_{MIT} on different bulk TiO₂ substrates.

The T_{MIT} in VO₂ is related to the V–V distance along the rutile c-axis, which affects the orbital overlap and the metallicity in the rutile phase. In the past, this had been studied as a function of film orientation, chemical doping, thickness and strain on TiO₂ substrates. For example, under compressive strain, the T_{MIT} of a 24 nm thick (001)R VO₂ film grown on TiO₂ decreased to 330 K, while it was the same as the bulk VO₂ value of 341 K for a fully relaxed 74 nm thick film. When the rutile c-axis is under tensile strain, similar to using TiO₂ (110) single crystal substrates, T_{MIT} is seen to increase to 350–369 K. Therefore, as T_{MIT} for VO₂ grown on TO nanosheets is higher than that of strain-free, bulk VO₂, this indicates that the R-VO₂ c-axis (2.86 Å when unstrained) is under a degree of tensile strain in the [010] direction of the TO nanosheet which has b = 2.97 Å. The situation is the other way around for the VO₂ grown on NWO nanosheets: here T_{MIT} is lower, suggesting compressive strain along the rutile c-axis, as could be expected from the Poisson effect given the tensile strain along the [100] and [010] directions of VO₂ (a = 4.53 Å) due to coupling to the NWO nanosheet (a = 4.68 Å).

The MIT of the TO-templated VO₂ shows a steep-sided hysteresis curve. In comparison, the data of Figure 4 show that the VO₂ grown on NWO nanosheets displays a relatively broad MIT. A
possible explanation for this observation could be related to the fact that the NWO-templated VO2 possesses a surface roughness of order 10 nm, compared to 2 nm for the TO-templated VO2 films (see Figure S1 (Supporting Information) for AFM data from the VO2 films). As the MIT in VO2 possesses a strongly percolative character,[29] the increased roughness, on top of an increased density of grain boundaries due to inter-nanosheet boundaries[17] can be at least a partial explanation of the broader transition for the case of VO2 grown on NWO nanosheet templates. In addition, the larger deviation from 90° bond angles of the 2D atomic structure of the (−402)M1 plane in the NWO case compared to the (011)M1 plane for TO-templated growth (see Figure 1) is also compatible with a larger domain/grain boundary contribution to the transport for the NWO-templated VO2.

From the experimental data thus far, it is clear that the nanosheets provide an elegant and effective method to control the orientation of VO2 films on two widely different bulk substrates. In order to both emphasize the added possibilities that freedom from “hard” substrate epitaxy enables, as well as to illustrate how this can also be controlled on the micrometer scale, the next section reports a new strategy to manipulate different orientations of VO2 on a single, arbitrary substrate. To do this, NWO nanosheets were lithographically line-patterned on top of a monolayer of TO nanosheets, with subsequent VO2 growth on this structured template layer to demonstrate the local manipulation of the orientation of the resulting high-quality VO2 film.

Figure 5 presents the high resolution scanning electron microscopy (HR-SEM) cross-sectional view of the line-patterned VO2, showing in panel (a) that the film thickness was roughly 50 nm on both types of nanosheets. In addition, the HR-SEM plan-view (Figure 5b) clearly reveals the different surface morphologies alluded to earlier on either side of the nanosheet boundary, consistent with the AFM data of VO2 films grown on “single species” TO and NWO nanosheets (see Figure S1, Supporting Information). In both situations the resulting VO2 film has a smoother surface on TO than on NWO nanosheets.

In addition to SEM imaging, EBSD maps were recorded, providing crystallographic information on the VO2 film on the lithographically patterned nanosheet layers, shown in Figure 5c,d. As these data were recorded at room temperature, we use in the following the M1 film orientations (the corresponding R-phase orientation was shown in Figure 2). The inverse pole figures reveal the out-of-plane orientations (−402)M1 (shown in gold color, becoming (002)R at elevated temperature) and (011)M1 (shown in purple, becoming (110)R at elevated temperature). Taking a closer look at a domain on single-typed nanosheet regions, the four inverse pole figures
of Figure 5e correspond to the four chosen regions indicated in Figure 5c. These show the presence of a single out-of-plane orientation for each type of nanosheet. It is evident that the VO$_2$ film out-of-plane orientations follow the underlying nanosheets with high fidelity, down to the micrometer level as we designed.

The in-plane EBSD orientation map displayed in Figure 5d shows a random orientational distribution, resulting from the randomness of in-plane orientation of nanosheets during LB deposition. On each single nanosheet, the reduced symmetry of the monoclinic VO$_2$ lattice when cooling down from the high-temperature rutile phase is expected to induce the formation of four in-plane structural domains. The inverse pole figures shown in Figure 5f show two of these because, due to symmetry (presence of a mirror plane) of the monoclinic phase, only half of the complete stereographic projection is displayed. Furthermore, in domain 2, only 1 orientation is seen as we are looking along the $2_1$ axis.

Having proven the excellent crystalline quality and the exquisite control over the orientation of VO$_2$ grown on nanosheets of different types, spectroscopy in the soft X-ray regime is now used to benchmark the epitaxial samples grown on TO nanosheets and provide comparison of the sample quality to what is known in the literature. As shown in the data of Figure 2c–f, the nanosheet approach enables deposition of high-quality VO$_2$ on Si$_3$N$_4$ membranes that are soft X-ray transparent, opening a route to conducting XAS in transmission. This yields a bulk-sensitive and direct measure of the absorption that can directly be correlated with local measurements carried out in the TEM. The majority of previous XAS studies...
of VO₂ have used indirect methods such as Total Electron Yield (TEY) to monitor the X-Ray absorption process.⁵,³¹–³⁵

Linking to the transport data presented in Figure 4, XAS at the vanadium-L₂,₃ (2p→3d transitions) and oxygen-K (1s→2p transitions) absorption edges also directly probe the MIT, and are readily accessible using soft X-rays provided by a synchrotron light source. In correlated transition metal oxides such as VO₂, the ability of soft X-ray spectroscopy to provide detailed information on the manifold and coupled degrees of freedom (e.g., lattice, spin, charge and orbital) using the transition metal-L₂,₃ and O-K edges have been studied extensively.⁵,³⁰–³⁵

Panel (a) of Figure 6 shows V-L₂,₃ edge data both for the metallic (rutile) and insulating (monoclinic) phases for the TO nanosheet templated VO₂. As reported by Aetukuri et al.,²⁷ the changes seen to occur across the MIT are related to the orbital occupation, and in particular they underscore the transformation of the 3D rutile situation to one in which V-dimers form along the direction of the rutile c-axis, leading to shifts and splitting of electronic states related to the orbitals polarized in this direction, referred to as the d₉ states. For grazing incidence (E⊥c_rutile) the temperature dependent changes shown in Figure 6b agree excellently with published data on films grown on single crystalline, bulk substrates,⁵ attesting to the quality of the nanosheet templated VO₂ thin films. Closer examination of the insets yields that the bulk (transmission) X-ray absorption spectroscopy (XAS) shows an onset of the MIT on warming at 340 K, and that ~40 K of further heating are required to complete the conversion to the rutile phase. The transport data shown in Figure 4 from fully analogous VO₂ films show an earlier onset and faster completion of the transformation on heating. This can be understood straightforwardly as resulting from the percolative nature of the transport probe on the one hand and to the bulk-sensitive, volume-fraction-driven absorption of soft X-ray radiation on the other hand.

One of the clear order parameters for the MIT is the opening of an energy gap in the insulating phase. This can be clearly seen in XAS at the O-K edge, as shown in Figures 6b and 7b,c, and reported in the literature recently.⁹ With reference to the electronic structure schematic shown under the data of Figure 6b, the most marked spectroscopic changes in the O-K edge spectra while entering the metallic phase are due to the closure of the gap, and the disappearance of the unoccupied d₉ states, the latter present in the monoclinic phase due to a splitting of the highly directional d₉ states. The insets to Figure 6b show how these changes to the gap [d₉] states leads to an increase (decrease) of the XAS absorption at the characteristic energy of 529.1 (530.6) eV.

Figure 7a illustrates the experimental configuration used for polarized XAS in transmission. For the TO-nanosheet-templated VO₂ films, the rutile c-axis is in the film plane, and its in-plane orientation varies from one nanosheet to the next. The synchrotron X-ray beam is large enough to average over a large number of nanosheets, meaning that we can consider vertically polarized radiation (LV) at grazing incidence to yield an unpolarized spectrum. Horizontally polarized radiation (LH) aligns the E-vector perpendicular to the film plane and hence E∥c_rutile is always realized, regardless of the direction of the in-plane orientation of the rutile c-axis in each individual nanosheet-templated epitaxial grain. In Figure 7b,c, polarization-dependent XAS spectra are shown for both grazing and normal incidence of the beam, respectively. As is clear from the earlier discussion, for normal incidence (Figure 7c), whether LV or LH radiation is used makes no difference to the absorption spectra, as in all cases a mixture of E∥c_rutile and E⊥c_rutile is the result. For grazing incidence (Figure 7b) and LH radiation, the E vector is E∥c_rutile compared to mixed E∥c_rutile and E⊥c_rutile for linear vertical. This is of high relevance for future experiments such as those outlined in Figure 8 in the next section. The major
advantages are the presence of: i) the O\text{K} leading edge shift at \( \approx 529 \text{ eV} \), ii) the directional \( d_{||}\text{rutile} \) states in the monoclinic phase at \( \approx 530.5 \text{ eV} \), and iii) the \( \sigma^* \) states in the rutile phase at \( \approx 531.5 \text{ eV} \) which all show up clearly in the transmission XAS measurements, also without the need of a full suite of polarization-dependent measurements.

Summarizing, we report on the successful deposition of high-quality vanadium dioxide thin films on Si substrates and Si\text{N}_4 membranes using oxide nanosheets of TO and NWO as a templating layer. Each nanosheet is a single crystal template, able to orient the growth direction of the VO\text{2} film as a result of lattice match of the oxygen frameworks of the two systems and compatibility of the 2D atomic structure between the nanosheets and the VO\text{2} crystal planes. X-ray diffraction, SEM imaging, EBSD, and ACOM-TEM data all agree on the film orientation, attesting to the epitaxial relationship such that TO nanosheets template (110)\text{R} growth and NWO templates (002)\text{R} growth of VO\text{2}. It was also shown that even micrometer-scale, local control over the VO\text{2} orientation is achievable, when using lithographically patterned nanosheet templates on a single, monolithic substrate.

The second main strand in the research presented deals with the MIT of the nanosheet templated VO\text{2} films. Due to strain effects along the \( c \)-axis of VO\text{2} rutile phase, \( T_{\text{MIT}} \) was 10 K higher (9 K lower) on TO NWO nanosheets, compared to bulk VO\text{2} single crystal values. Truly bulk-sensitive soft X-ray experiments carried out in transmission also underlined the excellent quality of the VO\text{2} thin films, which displayed all the hallmarks of the MIT known from films grown on bulk substrates. The significant soft X-ray transmission contrast—for example, at the O\text{K} leading edge, or at the position of \( d_{||}\text{feature} \)—combined with the ability to work in transmission, means such nanosheet templated VO\text{2} films are ideal for advanced soft X-ray techniques such as lensless imaging of the MIT with spatial resolution of tens of nm. Such techniques involve holographic reconstruction of the real-space patterns formed during the MIT, and can be carried out on a modified version of the samples used for the studies reported here. Figure 8 shows a schematic for such an experiment. We have taken the first step toward such experiments and have recently successfully reconstructed first images during the MIT of VO\text{2} using the holography with extended reference by autocorrelation linear differential operator reconstruction technique.\[36–38\]

3. Conclusions

To conclude, we have shown that nanosheets can act as templates for heteroepitaxial growth of high-quality VO\text{2} thin films on arbitrary substrates. The latter can be amorphous or have a very different crystallographic structure compared to the target material VO\text{2} itself. This approach allows this important test-case material for oxide-based devices and switching to be grown tailored for specific device applications and for fundamental research. An example is given of how microstructured areas of differing VO\text{2} orientation can be generated, and how the nanosheet-templated growth approach can be used to enable soft X-ray holographic lensless imaging of the MIT in VO\text{2}. 

Figure 7. V orbital occupancy across the MIT. a) Schematic of soft X-ray absorption experiments on TO-nanosheet-supported VO\text{2} thin films grown on 20 nm thick silicon nitride TEM windows. Linearly polarized synchrotron radiation impinges in grazing incidence, as indicated (the transmitted beam is measured using a diode downstream of the sample, not shown). The \( c \)-axis of the (110)\text{R} VO\text{2} film is oriented differently in each of the nanosheet domains, but is always in the plane of the film. Therefore, LH fixes \( E_{||}\text{rutile} \) and LV polarization probes a mix of \( E_{\perp}\text{rutile} \) and \( E_{||}\text{rutile} \). Polarization-dependent measurements at the O\text{K} edge above and below the transition for both b) grazing and c) normal incidence show the in-plane polarization of the unoccupied portion of the highly directionally aligned \( d_{||}\) states.
Figure 8. Lensless imaging of the MIT of VO₂. Schematic of a soft X-ray holography experiment on nanosheet-supported VO₂ thin films that incorporate with a gold mask structure. The VO₂ films can be grown using PLD on TO nanosheets that are deposited on commercial, 200 nm thick silicon nitride TEM windows (e.g., Simgore). A gold mask is subsequently deposited and a sample window (diameter 2 μm) + reference slit are machined into the mask using a focused ion beam (FIB). The window reveals the VO₂ film, whereas the slit goes right through the whole structure (including the VO₂, the nanosheets, and silicon nitride, too). Illumination with coherent X-rays yields a far-field diffraction pattern, and using a differential filter and fast Fourier transform it is possible to reconstruct a real space image of the different phases of VO₂ during the MIT. At an X-ray free electron laser, sufficient intensity in a single ultrafast flash of X-rays would also allow a pump-probe version of this experiment, so enabling a stop-motion film to be built up of how VO₂ switches on both the fs timescale and nm length scales.

4. Experimental Section

Preparation of Nanosheet Films: Potassium carbonate K₂CO₃ (Fluka), lithium carbonate Li₂CO₃ (Riedel-de Haen), titanium (IV) dioxide TiO₂ (Sigma-Aldrich), niobium (V) oxide Nb₂O₅ (Alfa Aesar), and tungsten (VI) oxide WO₃ (Alfa Aesar) had a purity of 99.0% or higher and were used as received. Nitric acid (HNO₃; 65%, ACROS Organics) and hydrofluoric acid (HF, 48%, Aldrich) were used as received. Demineralized water was used throughout the experiments.

K₀.₈T₁₇L₁₄₂₇O₄ and LiNbWO₄ were synthesized as reported in the literature,[39,40] and the layered protonated titanate, H₁₊₇T₁₇O₄·H₂O, and protonated HNbWO₆·xH₂O were obtained by treating with 2 M HNO₃ for 3 d and replacing new acid solution every day. The rapid exfoliation with TBAOH, which has been reported for H₁₊₇T₁₇O₄·H₂O,[41] was also observed for HNbWO₆·xH₂O. Full-coverage TO and NWO nanosheet films were generated on Si substrates and Si₃N₄ TEM grips using the LB method.

The micrometer-scale patterned nanosheet template combining TO and NWO nanosheets was prepared as follows. A monolayer of TO nanosheets was deposited on a Si substrate. On top of this monolayer, hexamethyldisiloxane (Merck) was spin-coated at 3000 rpm for 30 s and then a thick layer of photoresist (OIR 907–12 from Olin Microelectronic Materials Inc.) was spin-coated at 3000 rpm for 30 s. After heating at 90 °C for 2 min, the sample was exposed to a Hg lamp with a wavelength of 365 nm for 10 s under a 20 μm spaced line gratings mask (in a Karl Suss MA56 Mask Aligner). The photoresist was developed using OPD 4262 (Arch Chemicals) and baked at 110 °C for 2 min. Subsequently, a monolayer of NWO nanosheets was deposited on this line-patterned sample. Lastly, the sample was dipped and held upside-down in acetone for 1 min for lift-off, in order to remove the NWO nanosheets on top of the photoresist. The sample was then rinsed with ethanol and dried in a N₂ gas stream.

Pulsed Laser Deposition of VO₂ Thin Films: PLD was carried out in a vacuum system equipped with a KrF excimer laser, with a wavelength of 248 nm (COMPEX from Coherent Inc.). The central part of the laser beam was selected with a mask and focused on a polycrystalline V₂O₅ target. The deposition conditions of the VO₂ films were laser repetition rate 4 Hz, energy density 1.3 J cm⁻², spot size 1.8 mm², oxygen pressure 7.5 mTorr, deposition temperature 520 °C, number of pulses 15 000, and substrate-target distance 50 mm. After deposition, the samples were cooled down to room temperature at a maximum rate of 5 °C min⁻¹ at the deposition pressure.

Analysis and Characterization: The surfaces of the nanosheet films and of the VO₂ on Si substrates were investigated using AFM (Bruker Dimension ICON) operating in tapping mode and the data were processed using Gwyddion software (version 2.48).[42] The relative coverage of nanosheets on substrates was determined at four different locations. The temperature-dependent crystal structure of VO₂ thin films was analyzed using XRD θ–2θ scans (PANalytical X’Pert Pro MRD) equipped with an Anton Paar DHS 1100 Domed Hot Stage. The temperature dependence of the resistance was measured using a Quantum Design Physical Properties Measurement System. A two-probe measurement was performed to extract the MIT behavior, hysteresis, and transition temperature. HR-SEM and EBSD were performed on a Merlin field emission microscope (Zeiss 1550) equipped with an angle-selective backscatter detector at room temperature. The ACOM-TEM mode was acquired on an FEI Tecnai G2 microscope (FEG, 200 kV), equipped with the ASTAR system from Nanometrics. Electron precession was applied to acquire quasi-kinemical data and to facilitate automated indexation. The precession angle used of 0.4° yielded an electron probe size of ~1.5 nm. Interface mapping was achieved in post treatment with the orientation imaging microscopy (OIM) analysis software from Ametek EDAX company, including noise reduction and texture analysis. Misindexed or nonindexed points were corrected using a standard EBSD pattern collection procedure. Furthermore, grains smaller than 5 pixels or with a low reliability (<10%) were removed from the analysis. The pole figures were calculated using the harmonic series expansion and were generated along the common directions (001, 110, etc.) with the Gaussian half-width set at 5°. The average orientation was taken from every identified grain.

Soft X-ray transmission experiments were carried out on the JEOL-5601 at the BESSY II synchrotron source located at the Helmholtz Centre HZB in Berlin. Linearly polarized X-rays (horizontal and vertical) were generated using the UE56 GGM1 beamline at the BESSY II synchrotron source located at the Helmholtz Centre HZB in Berlin. Linearly polarized X-rays (horizontal and vertical) were generated using the UE56 helical undulator, and the energy resolution of the beamline was set to 80 meV. The sample temperature was carefully controlled using a Janis cryostat, and the transmission of X-rays was monitored by comparing photon flux monitors before (refocusing mirror current) and after the sample (on a diode), and included correction for mirror/diode contamination by division with an “empty scan” in which no VO₂ sample is held in the beam path. The soft X-ray lensless imaging experiments were conducted using the COMET end-station at the SEXTANTS beamline of the SOLEIL synchrotron.[43]
