Cavernous hemangioma accounts for 5% to 12% of all spinal vascular anomalies [1] and mainly occur in the vertebral body. Therefore, intradural extramedullary cavernous hemangioma are rare compared with vertebral body, epidural, and intramedullary cavernous hemangioma [2], with hemorrhagic transformation being very rare. Hemorrhagic transformation exacerbates the patient’s neurological symptoms. In our case, the patient had a sudden neurological deterioration. Here, we report a case of hemorrhagic transformation of cavernous hemangioma presenting with sudden paraplegia, and have added the pertinent literature review.

Case Report

A 57-year-old male with a week-long low back pain and right radiculopathy had been treated at a local hospital. However, the patient was admitted to our emergency room, presenting with paraplegia that suddenly occurred 3 days prior. During physical examination, the motor power of the right lower extremity was at Medical Research Council (MRC) grade 3. Sensory deficit was at hypoesthesia below the T11 level. Bowel and bladder function were normal, as well as the rectal examination results. The patient’s previous medication, medical history, and family history were unremarkable. Computed tomography at the T10–11 level showed a round isodense mass lesion. Magnetic resonance imaging (MRI) showed 1.2-cm oval intradural extramedullary mass. The T1-weighted image exhibited an isosignal (Fig. 1A), whereas the T2-weighted image showed a heterogeneous high signal on the sagittal and axial views (Fig. 1B, 1C). Moreover, the contrast-enhanced T1-weighted image showed homogenous enhancement (Fig. 1D). The MRI signals of cavernous hemangiomas can exhibit various signals depending on the hemorrhage period. Therefore, we suspected a differential diagnosis of schwannomas and meningiomas, with high incidence. Because of the sudden neurological symptom, emergency surgery was performed under neuromonitoring. After performing T10–11 laminectomy and upon the opening of the dura, the tumor exhibited active subdural hemorrhage when the dura was opened after T10–11 laminectomy. The tumor had brown and reddish colorations. The diagnosis of cavernous hemangioma was made based on a pathological examination, which showed a dilated and congested vascular space lined by endothelial cells. Hemorrhagic transformation of a cavernous hemangioma can worsen a patient’s condition. Therefore, before surgery, we should consider the possibility of other tumors, such as cavernous hemangiomas, as well as common intradural extramedullary tumors.

Keywords: Cavernous hemangioma; Spinal cord neoplasm
active bleeding in the subdural space. The tumor showed brown and reddish overall coloration. An en bloc resection was subsequently performed (Fig. 2). After surgery, the patient improved to an MRC grade 4. The diagnosis of cavernous hemangioma was made during pathological examination, which showed dilated and congested vascular space lined by endothelial cells (Fig. 3).

This study was reviewed and approved by the Institutional Review Board of Pusan National University Yangsan Hospital (IRB No. 05-2021-111). Due to its retrospective nature, the study was exempt from requiring informed consent from the participants.

**Discussion**

Spinal intradural extramedullary tumors account for two-thirds of all spinal tumors. Of these, 50% are meningiomas, 40% are schwannomas, and 10% are other tumors [3,4]. In the spine, the majority of cavernous hemangiomas are found in the vertebrae, with approximately 3% being intradural, and most of intradural cavernous hemangiomas being intramedullary [5]. Extramedullary tumors are hence very rare, and hemorrhagic transformation of hemangiomas rarely cause sudden neurological symptoms.

Hemangioma is a histological feature divided into capillary hemangioma and cavernous hemangioma. Cavernous hemangioma is a benign vascular lesion with an irregular sinusoidal dilated vascular channel that has a thin collagenous wall. Moreover, it has a single layer of endothelium without an arterial feature, and no elastic and smooth muscle fibers can be observed on the blood vessel walls [6–8]. In the present case, histologically cavernous hemangioma was diagnosed with a dilated and congested vascular space lined by endothelial cells.

In the spinal intradural extramedullary space, these tumors may arise from the blood vessels of the nerve roots in the cauda equina, the inner surface of the dura, or the pial surface of the spinal cord [5]. In the present case, the dura attachment site was checked (Fig. 4). Therefore, we thought of it as an intradural extramedullary tumor.

Intradural extramedullary cavernous hemangioma is mostly male dominant and occurs mainly at the thoracic level. Most clinical symptoms are accompanied by back pain and exhibit radiculopathy. It is also characterized by space-occupying masses, but the...
sensitive to hemorrhage. By contrast, calcium contrast-enhanced images generally show low signals, but could exhibit variability with factors such as hemorrhage, hemosiderin, and calcification. Spinal intradural extramedullary cavernous hemangioma have been reported in 30 cases, 10 of which presented with spinal sub-arachnoid hemorrhage \[10\]. In the present case, subarachnoid hemorrhage was not observed and acute subdural hemorrhage was seen instead. Jin et al. \[11\] reported that 25% of surgical patients with spinal intradural extramedullary cavernous hemangioma did not have improved symptoms. In the present case, total excision was implemented. The patient’s symptoms improved and he was then discharged.

Only the surgical removal of the tumor can improve symptoms and prevent disease progression. Moreover, when the neurological symptoms worsen, surgery should be hastened.

The present case is an unusual intradural extramedullary cavernous hemangioma hemorrhage transformation, which required accurate diagnosis and rapid surgery due to the sudden exacerbation of the patient’s neurological symptoms. However, cavernous hemangioma is difficult to differentiate from other tumors using MRI. If intradural extramedullary tumor is suspected and surgery is implemented, cavernous hemangioma should be considered if some non-specific signal appears in the MRI. Moreover, rapid treatment seems to have a positive impact on the patient’s future prognosis.
