Abstract
We study a gas flow in the Laval nozzle, which is a convergent–divergent tube
that has a sonic point in its throat. We show how to obtain the appropriate
form of the tube, so that the acoustic perturbations of the gas flow in it satisfy
any given wave-like equation. With the help of the proposed method we find
the Laval nozzle, which is an acoustic analogue of the massive scalar field in
the background of the Schwarzschild black hole. This gives us a possibility
to observe in a laboratory the quasinormal ringing of the massive scalar
field, which, for special set of the parameters, can have infinitely long-living
oscillations in its spectrum.

1. Introduction

Massive fields in the vicinity of black holes have been studied during the last two decades
(see [1] for review). It was found that their behaviour is qualitatively different from the
behaviour of the massless fields. The response of a black hole upon any perturbations at late
times can be described by a characteristic spectrum of exponentially damped oscillations. The
spectrum of a massive field, for some particular values of the parameters, has oscillations
with a very small decay rate in their characteristic spectra. These oscillations, which behave
similarly to standing waves, were called quasiresonances [2, 3]. The asymptotic behaviour of
massive fields is also different: one observes the oscillating tails that decay as inverse power
of time, which is universal at asymptotically late times [4].

Yet, since massive fields are short-ranged, we cannot expect the observation of their signal
from black holes in near-future experiments. An attractive possibility for experimental study of
the massive fields in the background of a black hole is a consideration of the acoustic analogue.
This is a well-known Unruh analogue of a black hole [5], which is an inhomogeneous fluid
system, where the perturbations (sound waves) can be described by a Klein–Gordon equation
in the background of some effective curved metric [6].
The sound waves in a fluid can propagate from a subsonic region to a supersonic one, but they cannot go back. Therefore, sonic points in a fluid with a space-dependent velocity form a one-way surface for the sound waves, which is called the ‘acoustic horizon’ due to its similarity with the event horizon of the black hole.

The works of Unruh stimulated the study of various acoustic systems, such as:

(i) the ‘draining bathtub’ which is an analogue of a rotating black hole [7–10];
(ii) the Bose–Einstein condensate [11–14], which, in the regime when the thermal fluctuations can be neglected, allows the observation of a phonon analogue of the Hawking radiation [15–20];
(iii) the so-called optical black holes [21] due to sound waves in a photon fluid of an optical cavity and inside an optical fiber [22]; and others [23–26].

Within the analogue-gravity approach one considers hydrodynamical equations as field equations in some effective background, which is not a solution to the Einstein equations. Using this approach the one-dimensional perturbations in the Laval nozzle were studied in [27]. It was found that the perturbations of the gas flow in the Laval nozzle can be described by a wave-like equation with the effective potential, which depends on the form of the tube. The inverse problem for the correspondence of the form of the Laval nozzle to the Schwarzschild black holes has been solved in [28], where the form of the Laval was found in order to obtain an acoustic analogue for the perturbations of massless fields.

Here we describe a method, which allows us to find an appropriate form of the Laval nozzle for any given effective potential. We use this method to obtain the acoustic analogue of the massive scalar field in the background of the Schwarzschild black hole. This paper is organized in the following form. In section 2 we give the basic equations for a one-dimensional flow in the Laval nozzle and its perturbations. In section 3 we describe the numerical method, which allows us to find the appropriate nozzle form in order to mimic any given effective potential. In section 4 we apply the method to find the form of the Laval nozzle, which is an acoustic analogue of the massive scalar field in the Schwarzschild background and show the corresponding time-domain profiles. Finally, in the conclusion, we discuss the obtained results and open questions.

2. Basic equations

A perfect fluid in the Laval nozzle can be described by the continuity equation and the Euler equation, that read, respectively,

\[ \frac{\partial}{\partial t} (\rho A) + \frac{\partial}{\partial x} (\rho u A) = 0, \]
\[ \rho (\frac{\partial}{\partial t} + u \cdot \nabla) u = -\nabla p, \]

where \( \rho \) is the density of a gas, \( u \) is the fluid velocity, \( p \) is the pressure, and \( A \) is the cross-section area of the nozzle. Following [27] we assume that the fluid is isentropic and the pressure depends only on the density

\[ p \propto \rho^\gamma, \]

where \( \gamma \) is the heat capacity (\( \gamma = 1.4 \) for the air).

Assuming that the flux is irrotational \( \nabla \times \vec{v} = 0 \), the velocity can be expressed as \( \vec{v} = \nabla \Phi \), where \( \Phi = \int \vec{v} \, dx \) is the velocity potential, which satisfies the Bernoulli equation

\[ \frac{\partial}{\partial t} \Phi + \frac{1}{2} (\partial \Phi)^2 + h(\rho) = 0. \]
We study linear perturbations of the flux, i.e. we consider the fluid density \( \rho \) and the velocity potential \( \phi \) as
\[
\rho = \bar{\rho} + \delta \rho, \quad \bar{\rho} \gg |\delta \rho| \quad (5)
\]
\[
\Phi = \bar{\Phi} + \phi, \quad |\partial_x \bar{\Phi}| \gg |\partial_x \phi| \quad (6)
\]
where \( \bar{\rho} , \bar{\Phi} \) are the background dynamical quantities which satisfy (1) and (4), \( \delta \rho \) and \( \phi \) describe the perturbations, which are considered small so that we neglect the higher-order corrections.

We introduce the function \( H_\omega(x) \),
\[
H_\omega(x) = g^{1/2} \int dt \ e^{i\omega(t-a(x))} \phi(t, x), \quad (7)
\]
with
\[
g = \frac{\rho A}{c_s} \quad a(x) = \int |\nu| \, dx \quad (8)
\]
where \( c_s \) is the sound speed,
\[
c_s = \sqrt{\frac{d_p}{d\rho} = \sqrt{\frac{\gamma p}{\rho}}}. \quad (9)
\]
We find that \( H_\omega \) satisfies the Schrödinger-type wave-like equation
\[
\left( \frac{d^2}{dx^2} + \kappa^2 - V(x^*) \right) H_\omega(x^*) = 0 \quad (10)
\]
\[
V(x^*) = \frac{1}{g^2} \left[ \frac{g}{2} \frac{d^2 g}{dx^2} - \frac{1}{4} \left( \frac{dg}{dx^*} \right)^2 \right] \quad (11)
\]
with respect to the new variable
\[
x^* = \int \frac{c_0 c_s}{c_s^2 - \nu^2} \, dx, \quad (12)
\]
where \( \kappa = \frac{\omega}{c_0} \) and \( c_0 \) is the stagnation sound speed.

The coordinate \( x^* \) is the tortoise coordinate for the analogue black hole: \( x^* = -\infty \) at the throat and \( x^* = \infty \) corresponds to the spatial infinity (\( x = \infty \)).

Following [28], we measure \( A \) and \( \rho \), respectively, in the units of cross-sectional area at the throat (\( A_{\text{th}} \)) and the flux stagnation density (\( \rho_0 \)), and choose the arbitrary factor for the function \( g \) in such a way that
\[
g = \frac{\rho A}{2\rho^{(\gamma-1)/2}}, \quad A^{-1} = (1 - \rho^{(\gamma-1)})^{1/2}. \quad (13)
\]
Then the cross-section area can be expressed as a function of \( g \) as
\[
A = \frac{\sqrt{2}(2g^2)(1 - \sqrt{1 - g^{-2}})^{(1/2)(\gamma-1)}}{\sqrt{1 - \gamma - g^{-2}}}. \quad (14)
\]
We find also that
\[
\frac{\nu^2}{c_s^2} = \frac{2}{\gamma - 1} (2g^2 (1 - \sqrt{1 - g^{-2}}) - 1). \quad (15)
\]
Since the gas velocity is equal to the sound velocity at the acoustic horizon, we obtain
\[
g |_{\text{horizon}} = \frac{\gamma + 1}{2\sqrt{2\sqrt{\gamma - 1}}} = \frac{3}{\sqrt{5}}. \quad (16)
\]
3. The nozzle form from a given effective potential

Linear perturbations of a spherically symmetric black hole, after decoupling of the time and angular variables, can always be reduced to the following wave-like equation

$$\left(\frac{d}{dr^2} + \omega^2 - V(r^*)\right)R(r^*) = 0,$$

(17)

where the effective potential $V = V(r^*)$ depends on the parameters of the field and the black hole and the tortoise coordinate is defined as

$$r^* = \int \frac{dr}{f(r)},$$

(18)

where $f(r)$ depends on the parameters of the black hole.

In order to find the form of the Laval nozzle which is an acoustic analogue of the black hole perturbations we equate the tortoise coordinates and the effective potentials of the equations (10) and (17)

$$f(r)f'(r)g'(r) + f(r)g(r)^2 - \frac{f(r)^2g'(r)^2}{4g(r)^2} = V(r).$$

(19)

From $dx^* = dr^*$ and equations (15) and (12) we find the relation between the coordinate of the nozzle and the radial coordinate of the metric $r$:

$$dx = \frac{(\gamma + 1 - 4g(r)^2(1 - \sqrt{1 - g(r)^{-2}})) dr}{f(r)(\gamma - 1)\sqrt{2g(r)^2(1 - \sqrt{1 - g(r)^{-2}})}}.$$  

(20)

If $g(r)$ is known, from the equations (14) and (20), one can find the function $A(x)$, which describes the nozzle form.

In order to find $g(r)$ we make the substitution $g(r) = h(r)^2$. Then the differential equation (19) reads

$$f(r)^2h''(r) + f(r)f'(r)h'(r) - V(r)h(r) = 0.$$  

(21)

Since the function $f(r)$ vanishes at the event horizon $r = r_+$, the linear equation (21) always has a regular singular point there. Using the Frobenius method we expand the general solution to the differential equation near the event horizon as

$$h(r) = c_1 h_1(r) + c_2 h_2(r),$$

(22)

where $c_1$ and $c_2$ are arbitrary constants,

$$h_1(r) = (r - r_+)^{\lambda_1} \left(1 + \sum_{n=1}^{\infty} a_n (r - r_+)^n\right),$$  

(23)

$$h_2(r) = h_1(r) \ln(r - r_+) + (r - r_+)^{\lambda_2} \sum_{n=0}^{\infty} b_n (r - r_+)^n,$$

when $\lambda_1 - \lambda_2$ is an integer, and

$$h_2(r) = (r - r_+)^{\lambda_2} \left(1 + \sum_{n=1}^{\infty} b_n (r - r_+)^n\right),$$

otherwise, $\lambda_2 \leq \lambda_1$ are the roots of the indicial equation and depend on the given functions $f(r)$ and $V(r)$.

In order to satisfy (16), one of the roots must be zero. $f'(r_+) > 0$ implies that the other root is negative. Hence, for $\lambda_2 \leq \lambda_1 = 0$, $h_2(r)$ is always divergent at the horizon $r = r_+$ and we choose $c_2 = 0$. Therefore, from (16) we find that
We expand (23) near the event horizon and find \( h'(r+) \), which completely fixes the initial value problem at \( r = r_+ \). Then, we are able to solve numerically the equation (21) using the Runge–Kutta method for \( r > r_+ \).

4. Acoustic analogue for the massive scalar field

We consider the massive scalar field in the background of the Schwarzschild black hole, given by the line element

\[
d s^2 = f(r) \, d t^2 - \frac{r^2 (d \theta^2 + \sin^2 \theta \, d \phi^2)}{f(r)},
\]

where \( f(r) = 1 - \frac{2M}{r} \), \( M \) is the mass of the black hole. Hereafter we measure all the quantities in units of the black hole horizon, i.e. \( r_+ = 2M = 1 \).

The scalar field \( \Psi \) satisfies the Klein–Gordon equation

\[
(\nabla^\mu \nabla_\mu + m^2)\Psi = 0,
\]

where \( \nabla_\mu \) is the covariant derivative, \( m \) is the field mass. The equation (25) in the background (24) reads

\[
\frac{1}{\sqrt{|g|}} \partial_\mu (g^{\mu \nu} \sqrt{|g|} \partial_\nu \Psi) + m^2 \Psi = 0.
\]

After the separation of the angular and time variables

\[
\Psi(t, r, \theta, \phi) = R(r) Y_l^m(\theta, \phi) e^{-i\omega t},
\]

we obtain the wave-like equation (17) with the effective potential

\[
V(r) = f(r) \left( \frac{l(l+1)}{r^2} + \frac{f'(r)}{r} + m^2 \right).
\]

In order to show the time-domain evolution of perturbations we use the discretization scheme proposed by Gundlach et al [29]. We consider the time-dependent equation

\[
\left( \frac{d^2}{dr^2} - \frac{d^2}{dr^*} - V(r) \right) \Phi(t, r^*) = 0.
\]

Rewriting (29) in terms of the light-cone coordinates \( du = dr - dr^* \) and \( dv = dr + dr^* \), we find that

\[
\Phi(N) = \Phi(W) + \Phi(E) - \Phi(S) - \frac{h^2}{8} V(S) [\Phi(W) + \Phi(E)] + O(h^4),
\]

where the point \( N, M, E \) and \( S \) are the points of one square in a grid with step \( h \) in the \( u–v \) plane, as follows: \( S = (u, v), W = (u + h, v), E = (u, v + h) \) and \( N = (u + h, v + h) \). With the initial data specified on two null-surfaces \( u = u_0 \) and \( v = v_0 \) we are able to find values of the function \( \Psi \) at each of the points of the grid.

In figures 1 and 2 we show the forms of the nozzle that are acoustic analogues of the massive field with particular values of the mass for which nearly infinitely long-living oscillations exist. One can observe these oscillations, called quasiresonances, on the corresponding time-domain profiles. We see that in the tube of a particular form the decay rate of sound waves is almost zero for some tone, which is an analogue of the quasiresonance of the massive scalar field.
From (7) one can observe that the massive-field wavefunction is related to its analogue in the Laval nozzle through a non-trivial relation. Namely, each oscillation of the quasinormal spectrum is multiplied by a function, which depends on its proper frequency. This leads to different amplitudes of the corresponding oscillations in the signal and its analogue.
Nevertheless, since the late-time behaviour of the quasinormal ringing does not depend on the initial perturbations, we can state that the time-domain profiles presented in figures 1 and 2 describe the time-domain evolution of the massive scalar field in the background of a Schwarzschild black hole as well as perturbations of a fluid in the corresponding Laval nozzle. It is interesting to note also that for the quasiresonances, for which the corresponding frequencies are purely real, the transformation (7) does not change the absolute value of their amplitudes.

Although we present here only the nozzles where the quasiresonances can be observed, the method described above can be used to construct an analogue for any finite field mass in such a way that the sound waves in the nozzle will have the same behaviour as the massive scalar field in the background of the Schwarzschild black hole. From figures 1 and 2 one can observe that the higher the mass is, the quicker the nozzle cross-section grows, diverging at the end. However, as was pointed out in [28], this does not lead to a problem with the presented model because of the freedom of the choice of the units of length. One can rescale the nozzle along the transversal axis in order to make the cross-section change as slowly as one wants. This change of the scale changes proportionally the frequencies of the sound in the nozzle.

5. Conclusion

We have considered the Laval nozzle as an acoustic analogue of the massive scalar field in the background of the Schwarzschild black hole. We presented the general method to determine the form of the Laval nozzle, such that the sound waves in it are described by a given effective potential, that can be used to study an analogue of black hole perturbations in a laboratory. One should also note that the analogue between the massive field and the perturbations in the Laval nozzle is not precise. Although the shape of the nozzle produces the effective potential for the massive field, the sound wave remains ‘massless’, i.e. its propagation speed is always \( c_s \). In order to obtain the potential, which asymptotically approaches a positive constant, we need to make the nozzle’s cross-section grow faster. The larger field mass is the faster cross-section of the corresponding nozzle grows, remaining, however, finite for any finite point.

Since the perturbation evolution is determined mainly by some region near the black hole [33], in practice, we can limit the nozzle’s length by some finite value, which must be large enough to neglect the influence of the bound. The method can be used to obtain the forms of the nozzles, which are acoustic analogues of other spherically symmetric black holes. The acoustic analogues for perturbations of Reissner–Nordström(–de Sitter) black holes and their higher-dimensional generalizations, black strings and Gauss–Bonnet black holes are of special interest. For some set of the parameters the higher-dimensional black holes and black strings suffer instability [30–32], which in the corresponding nozzle can manifest itself as an increasing of the sound amplitude. It is clear that for a large amplitude, the sound waves cannot be described within the linear approximation and the considered analogue between the linear perturbations cannot be applied. Nevertheless, we believe that the consideration of different physical systems, which have linear instability in the same parametric region, could help us to better understand its nature.
