Abstract

We apply the Meson Cloud Model to the calculation of nonsinglet parton distributions in the nucleon sea, including the octet and the decuplet cloud baryon contributions. We give special attention to the differences between nonstrange and strange sea quarks, trying to identify possible sources of $SU(3)$ flavor breaking. A analysis in terms of the $\kappa$ parameter is presented, and we find that the existing $SU(3)$ flavor asymmetry in the nucleon sea can be quantitatively explained by the meson cloud. We also consider the $\Sigma^+$ baryon, finding similar conclusions.

1 Introduction

The presence of a flavor asymmetry in the light antiquark sea of the proton is now clearly established \[1, 2\]. It can be expressed either in terms of the difference, \( \Delta(x) = \bar{d}(x) - \bar{u}(x) \), or in terms of the ratio, \( R(x) = \frac{\bar{d}(x)}{\bar{u}(x)} \). The fact that this difference is larger than zero (or that the ratio is larger than one) is usually referred to as \( SU(2) \) flavor symmetry breaking in the proton sea.

We will discuss in this paper the nonperturbative origin of the breaking of flavor symmetry, both at the \( SU(2) \) and at the \( SU(3) \) level. To this end, we will study the suppression factor of \( \bar{u} \) antiquarks in the \( SU(2) \) case, defined as

\[
\kappa(2) = \frac{\int_0^1 \frac{dx}{x} \frac{\overline{d}(x, \mu^2)}{\overline{u}(x, \mu^2)} \, dx \, \frac{d(x, \mu^2) - u(x, \mu^2)}{u(x, \mu^2)}},
\]

and the suppression factor of strangeness in the \( SU(3) \) case:

\[
\kappa(3) = \frac{\int_0^1 \frac{dx}{x} \frac{\overline{s}(x, \mu^2)}{\overline{s}(x, \mu^2)} \, dx \, \frac{s(x, \mu^2) + x\overline{s}(x, \mu^2)}{d(x, \mu^2) + x\overline{d}(x, \mu^2)}},
\]

We notice that in the limit of exact \( SU(2) \) (\( SU(3) \)) flavor symmetry \( \kappa(2) = 1 \) (\( \kappa(3) = 1 \)). The CCFR collaboration has measured \[3\] \( \kappa(3) \simeq 0.37 \pm 0.05 \) (\( 0.477 \pm 0.05 \)) in a LO (NLO) QCD analysis. Uncertainties apart, it is clear that there is a substantial violation of the \( SU(3) \) flavor symmetry. In the nonstrange light antiquark sector, the use of the standard parametrizations leads to \( \kappa(2) \sim 1.3 \) \[4, 5\], indicating also a strong violation of the \( SU(2) \) flavor symmetry in the proton sea. At the same time, the \( SU(2) \) charge symmetry is believed to hold within the baryon octet, i.e., \( \overline{d}(x) - \overline{u}(x) \) in the proton is equal to \( \overline{u}(x) - \overline{d}(x) \) in the neutron. An interesting question is how \( SU(3) \) charge symmetry is broken within the baryon octet. If the symmetry were exact, it would mean, for instance, that \( s(x) - \overline{s}(x) \) in the proton should be equal to \( d(x) - \overline{d}(x) \) in the \( \Sigma^+ \). However, as calculated by the authors of Ref. \[7, 8, 9\], this is not the case, and in this work we also investigate the origins of the breaking of this symmetry.

In QCD, exact \( SU(3) \) symmetry implies that the \( u, d \) and \( s \) quarks have the same mass. Since the strange quark mass, \( m_s \), is significantly larger than the up and down quark masses, the symmetry is only approximate. At the hadronic level, exact \( SU(3) \) symmetry also implies that the masses of baryons or mesons belonging to the same multiplets are all equal. Clearly this is not the case and the masses within the baryon multiplets differ
among themselves by more than 30%. The mass discrepancy is even more pronounced in the meson octet.

Another consequence of the $SU(3)$ symmetry at the hadronic level is that the coupling constant in a generic baryon-baryon-meson ($g\mathcal{B}\gamma_5\mathcal{B}M$) vertex should be the same for all $B$, $\bar{B}$ and $M$. Since these three states together must form a $SU(3)$ singlet state, and the mesons are usually in octet states, it follows that the product of the two baryon representations must also be in a $SU(3)$ octet state. Out of the $(\mathcal{B}\mathcal{B})$ product $8 \times 8$, we get two distinct octets and therefore two independent coupling constants. This is the origin of the two $SU(3)$ constants, $F$ and $D$. When we consider some particular baryon-baryon-meson vertices, additional (Clebsch-Gordan) factors appear, so that the final couplings are different from each other. However, exact $SU(3)$ symmetry imposes a well defined connections between them. Finally, analysis of experimental data determine the relation between $F$ and $D$ in terms of the parameter $\alpha_D$:

$$\alpha_D = \frac{D}{D + F} \simeq 0.64$$

We can make use of QCD Sum Rules (QCDSR) to calculate the above mentioned coupling constants $[11, 12]$. In this approach we are able to identify the $SU(3)$ breaking sources affecting the couplings, which are mainly the quark and hadron mass differences. The different values of the condensates and other QCDSR parameters also play an important role.

As for the origin of the asymmetry in the light antiquark distributions, there is now strong indications that part of the nucleon sea comes from fluctuations of the original nucleon into baryon-meson states, i.e., from the meson cloud $[13, 14, 15, 16]$. The Meson Cloud Model (MCM) is dominated by hadronic quantities like hadron masses and coupling constants. This bridge between the physics of parton distribution and the conventional hadron physics may also help us, by connecting one with the other, to understand both $SU(3)$ symmetry breaking at the hadron and parton levels.

## 2 Parton Distributions in the MCM

In what follows, we show the meson-baryon Fock decomposition of the proton and of the $\Sigma^+$. In the case of the proton, most of the material has been already presented elsewhere $[14, 15, 16]$. We include it here just for completeness. Parton distributions in the $\Sigma^+$
hyperon have been discussed in [4, 5, 6], and we will also address them in this work. This will enable us to make a close comparison between the proton and hyperon parton distributions.

2.1 The proton

As usual, we decompose the proton in the following possible Fock states:

\[
|p\rangle = Z \left[ |p_0\rangle + |p_0\pi^0\rangle + |n\pi^+\rangle + |\Delta^0\pi^+\rangle + |\Delta^+\pi^0\rangle + |\Delta^{++}\pi^-\rangle + |\Lambda K^+\rangle + |\Sigma^0 K^+\rangle + |\Sigma^0\star K^+\rangle + |\Sigma^+ K^0\rangle + |\Sigma^+\star K^0\rangle \right]
\]

where \(|p_0\rangle\) is the bare proton. We consider only light mesons. The relative normalization of these states is, in principle, fixed once the cloud parameters are given. The normalization constant \(Z\) measures the probability to find the proton in its bare state.

In the \(|MB\rangle\) state, the meson and the baryon have fractional momentum \(y_M\) and \(y_B\), with distributions \(f_{M/MB}(y_M)\) and \(f_{B/MB}(y_B)\), respectively. Of course \(y_M + y_B = 1\) and these distributions are related by:

\[
f_{M/MB}(z) = f_{B/MB}(1 - z)
\]

The splitting function \(f_{M/MB}(y)\) represents the probability density to find a meson with momentum fraction \(y\) of the nucleon and is usually given by

\[
f_{M/MB}(y) = \frac{g_{MBp}^2}{16\pi^2} y \int_{-\infty}^{t_{\text{max}}} dt \frac{\left[-t + (M_B - M_p)^2\right]}{\left[t - m_M^2\right]^2} F_{MBp}^2(t),
\]

for baryons (B) belonging to the octet, and

\[
f_{M/MB}(y) = \frac{g_{MBp}^2}{16\pi^2} y \int_{-\infty}^{t_{\text{max}}} dt \frac{\left[(M_B + M_p)^2 - t\right]^2\left[(M_B - M_p)^2 - t\right]}{12M_B^2M_p^2\left[t - m_M^2\right]^2} F_{MBp}^2(t)
\]

for baryons belonging to the decuplet. In the calculations we need the baryon-meson-baryon form factors appearing in the splitting functions. Following a phenomenological approach, we use the dipole form:

\[
F_{MBp}(t) = \left(\frac{\Lambda_{MBp}^2 - m_M^2}{\Lambda_{MBp}^2 - t}\right)^2
\]
where $\Lambda_{MBp}$ is the form factor cut-off parameter. In the above equations $t$ and $m_M$ are the four momentum square and the mass of the meson in the cloud state, $t_{max}$ is the maximum $t$ given by:

$$t_{max} = M_p^2 y - \frac{M_B^2 y}{1 - y},$$

where $M_B$ ($M_p$) is the mass of the baryon (proton). Since the function $f_{M/MB}(y)$ has the interpretation of a flux of mesons inside the proton, the corresponding integral

$$n_{M/MB} = \sum_{MB} \int_0^1 dy \ f_{M/MB}(y),$$

can be interpreted as the number of mesons in the proton, or the number of mesons in the air. In many works, the magnitude of the multiplicities $n_{M/MB}$ has been considered as a measure of the validity of MCM in the standard formulation with $MB$ states. If these multiplicities turn out to be large ($\simeq 1$) then there is no justification for employing a one-meson truncation of the Fock expansion, as the expansion ceases to converge. This may happen for large cut-off values.

Once the splitting functions (6) and (7) are known we can calculate the antiquark distribution in the proton coming from the meson cloud through the convolution:

$$\overline{q}_f(x) = \sum_{MB} \int_x^1 \frac{dy}{y} f_{M/MB}(y) \overline{q}^M_f \left( \frac{x}{y} \right)$$

where $\overline{q}^M_f(z)$ is the valence antiquark distribution of flavor $f$ in the meson. An analogous expression holds for the quark distributions. With the above formula we can compute the $\overline{d}$ and $\overline{u}$ distributions, their difference, $\overline{d}(x) - \overline{u}(x)$, and hence the Gottfried integral:

$$S_G = \frac{1}{3} - \frac{2}{3} \int_0^1 [\overline{d}(x) - \overline{u}(x)] dx$$

Since we are interested in determining the sources of $SU(3)$ symmetry breaking, we also study the parton distributions in the case where the $SU(3)$ symmetry is exact. In our case, this is the limit in which we take all the meson and baryon masses to be the same in the $SU(3)$ multiplets. All other ingredients are, from the start, compatible with $SU(3)$ symmetry, i.e., all coupling constants follow $SU(3)$ relations [17], and the cut-off parameters are the same for a given multiplet. Of course, the nonstrange subset of these couplings respects the $SU(2)$ (isospin) symmetry.
The masses are $m_p = m_n = 938 \text{ MeV}$, $m_\pi = 138 \text{ MeV}$, $m_K = 480 \text{ MeV}$, $m_\Delta = 1232 \text{ MeV}$, $m_\Lambda = 1116 \text{ MeV}$, and $m_\Sigma = 1189 \text{ MeV}$. The octet coupling constants are given by the expressions in Table I [17], where $g_{p\pi^n_p} = -13.45$ [18, 19] and $\alpha_D$ was given in eq. (3). For the decuplet coupling constants, in Table II, where $g_{p\Delta^0_p} = \frac{28.6}{\sqrt{6}}$ [20, 21], we also use the standard $SU(3)$ relations between the couplings [17].

| $g_{pK^+\Lambda}$ | $-\frac{1}{\sqrt{3}} (3 - 2\alpha_D)g_{p\pi^0_p}$ |
|-------------------|-----------------------------------------------|
| $g_{pK^0\Sigma^0}$ | $(2\alpha_D - 1)g_{p\pi^0_p}$ |
| $g_{pK^0\Sigma^+}$ | $\sqrt{2}(2\alpha_D - 1)g_{p\pi^0_p}$ |
| $g_{p\pi^+n}$ | $\sqrt{2}g_{p\pi^0_p}$ |

**Table I:** Octet coupling constants.

| $g_{p\Sigma^0K^+}$ | $\frac{\sqrt{2}}{2}g_{p\Delta^0\pi^0}$ |
|-------------------|-------------------------------------------|
| $g_{p\Sigma^+K^0}$ | $g_{p\Delta^0\pi^0}$ |
| $g_{p\Delta^0\pi^0}$ | $\sqrt{2}g_{p\Delta^0\pi^0}$ |
| $g_{p\Delta^{++}\pi^-}$ | $\frac{\sqrt{3}}{2}g_{p\Delta^0\pi^0}$ |

**Table II:** Decuplet coupling constants.

Many of the works [14, 15, 16] done so far on this subject indicate that the cut-off parameters must be soft ($\Lambda \simeq 1 \text{ GeV}$ in dipole form). Indeed, in our attempt to have a simultaneous description of both the difference $\Delta(x)$ and the ratio $R(x)$, we find that

$$\Lambda_{oct} = 1.11 \text{ GeV} ; \quad \Lambda_{dec} = 1.07 \text{ GeV} ,$$

where $\Lambda_{oct}$ and $\Lambda_{dec}$ are the cut-off parameters for all the octet and decuplet vertices respectively. We notice that the ratio and the difference are related by [1]:

$$R(x) = \frac{1 + \Delta(x)/\Sigma(x)}{1 - \Delta(x)/\Sigma(x)} ,$$

where $\Sigma(x) = \overline{d}(x) + \overline{u}(x)$ is the total distribution, which may be taken from any of the available parametrizations of the parton distributions. We see from the dashed lines of Figs. 1a and 1b, that it is not possible to have a simultaneous description of the ratio and of the difference using the MCM only. Additional, nonperturbative physics is necessary, and we will discuss this point below. Before that, we point out that it is crucial
for our discussion of $SU(3)$ symmetry breaking that the cut-off parameters be the same
for all the members of the multiplets, including the cut-offs involved in the production
of strangeness. Their exact values could be different, provided that all the constraints
imposed by convergence of the Fock expansion, by data on inclusive meson production or
any other experimental information, be satisfied. In any case, we stress that the whole
set of cut-offs were fixed in the reproduction of the E866 data, and the results presented
here, which includes the strange sector, are predictions of the model.

As we noticed before, there should be some extra, nonperturbative, physics in order
to describe the full E866 data points. The natural step to take is to consider effects from
the Fermi statistics of the quarks, as suggested long ago by Field and Feynman [22], and
implemented recently in a quantitative way [15]. The idea is quite straight: as the proton
is, primarily, a $uud$ state, it should be easier to insert a $d$ pair than a $u\bar{u}$ pair in the
proton sea. This follows from the fact that there are more empty states for the insertion
of a $d$ quark than for the insertion of a $u$ quark. Following Ref. [15], we parametrize this
Pauli Blocking (PB) contribution by:

$$ (\bar{d} - \bar{u})_{PB}(x) = \Delta_{PB}(n + 1)(1 - x)^n. \tag{15} $$

As part of the nonperturbative sea, the PB contribution is added to the $\bar{d}(x) - \bar{u}(x)$
difference coming from the meson cloud, computed from Eq. (14).

The dashed lines in Figs. 1a and 1b show the combined effect of meson cloud and
PB effects for the $\bar{d}(x) - \bar{u}(x)$ and for $\bar{d}(x)/\bar{u}(x)$, as a function of $x$, using $\Delta_{PB} = 0.017$
and $n = 10$. The data points are from the E866 collaboration [1, 2], where the CTEQ
parametrization for $\bar{u}(x) + \bar{d}(x)$ was used in Eq. (14) to relate $\Delta(x)$ to $R(x)$. Our results
confirm analogous calculations performed previously by Melnitchouk, Speth and Thomas
[15], although we see that the size of our PB is significantly smaller.

When working with the sea parton distributions it should be emphasized that in dif-
fferences such as $\bar{d}(x) - \bar{u}(x)$ or $\bar{s}(x) - \bar{u}(x)$ the perturbative contributions should cancel
if the production of sea partons from hard gluons is to be insensitive to small masses,
including the strange quark mass. Such a property was already used in the writing of Eq.
(14). Therefore, any deviation of $\kappa(2)$ and $\kappa(3)$ from 1 (or $x(\bar{d}(x) - \bar{u}(x))$, etc, from zero),
must have a nonperturbative origin. As the meson cloud is the main nonperturbative con-

\[^1\text{As shown in [23, 24], possible antisymmetrization effects between the sea and the valence quarks can}
\text{spoil this naive counting.}\]
tribution, it should be quite reliable when calculating the differences of sea distributions. Figure 1 supports this view. The ratios, on the other hand, also include the (dominant) perturbative contribution. Thus, in order to calculate \( \kappa(2) \) including this contribution, we use the fact that \( \int_0^1 x (d(x) - \bar{u}(x))\,dx \neq 0 \) from nonperturbative effects only, and rewrite Eq. (1) as:

\[
\kappa(2) = 1 + \frac{\int_0^1 x \, [d(x) - \bar{u}(x)]^{NP}}{\int_0^1 x \, \bar{u}(x)} \tag{16}
\]

where in the denominator we have used the CTEQ4 parametrization \[6\] for the integral of the \( \bar{u} \) antiquark distribution. The obtained value is

\[
\kappa(2) = 1.22, \tag{17}
\]

compatible with the values quoted in the introduction.

For the Gottfried sum rule (12), we obtain \( S_G = 0.255 \), which is to be compared with the experimental value \( 0.235 \pm 0.026 \), obtained by the E866 collaboration \[1, 2\]. The calculation of the multiplicities through Eq. (10) give

\[
n_{\pi N} \simeq 0.30 \quad \text{and} \quad n_{\pi \Delta} \simeq 0.27.
\]

Before moving to the strange sector, it is worth noticing that this value of \( \kappa(2) \) indicates a violation of \( SU(2) \) flavor inside the proton which is not in conflict with the \( SU(2) \) charge symmetry between the proton and the neutron. The \( SU(2) \) charge symmetry still holds in the MCM. In order to check this, it is enough to write the dominant terms of the Fock expansion for the neutron cloud

\[
|n> = Z \left[ |n_0> + |n_0\pi^0> + |p\pi^-> + |\Delta^0\pi^0> + |\Delta^+\pi^-> + |\Delta^-\pi^+> \right], \tag{18}
\]

and realize that, since our coupling constants respect \( SU(2) \), it follows that \( g_{n\pi^-} = g_{p\pi^+} \), \( g_{n\Delta^-\pi^+} = -g_{p\Delta^+\pi^-} \), and \( g_{n\Delta^+\pi^-} = -g_{p\Delta^0\pi^+} \). When we substitute these relations in Eq. (11), and use \( m_p = m_n \), we arrive at the conclusion that \( \bar{d}(x) - \bar{u}(x) \) in the proton is exactly the same as \( \bar{u}(x) - \bar{d}(x) \) in the neutron.

In Figs. 2a, 2b and 2c we show, respectively, \( xs(x) \) (compared to \( x\bar{s} \)), \( x(s(x) - \bar{s}(x)) \) (decomposed in its octet and decuplet contributions), and \( s(x) - \bar{s}(x) \) as functions of \( x \). We made the assumption that the valence \( s(x) \) distribution in the hyperons is the same as the valence \( d(x) \) distribution in the proton. The \( s(x) \) quark distribution is harder than the \( \bar{s}(x) \) distribution because it is inside a (harder) strange baryon in the cloud, a conclusion corroborated by other authors \[23, 24\]. In Fig. 2b we can appreciate how significant the
decuplet contribution is for the $x(s(x) - \bar{s}(x))$ asymmetry, which is plotted in Fig. 2c against the experimental result (shaded area) [3].

In Fig. 3 we show $\bar{s}(x) - \bar{u}(x)$ in the proton. The points represent the parametrizations CTEQ4L (full circles), GRV98LO (open circles) and MRS99-1(squares) and the solid line shows the MCM result. The dashed and dotted lines show the octet and decuplet contributions to the meson cloud, respectively. From this figure we can see that the decuplet contribution is sizeable, and therefore it should be included in any study of nonsinglet quantities involving the strange sea quark distributions.

When extending our analysis from 2 to 3 flavors, we can define a quantity analogous to the $\bar{d}(x) - \bar{u}(x)$ difference, i.e., a quantity which measures how blocked is the production of strange quarks compared to the nonstrange quarks: $\bar{d}(x) + \bar{u}(x) - s(x) - \bar{s}(x)$. Notice that, from the point of view of perturbative QCD, this quantity should be zero (besides, perhaps, some small mass effects, which should not be relevant in the intermediate or small $x$ region). Hence, if our current view of the nonperturbative proton sea, as generated from mesons and from Pauli blocking, is correct this difference should also be well described by the MCM. We show our results in Fig. 4, and we see that our MCM curve (solid line) is compatible (although on the edge) with the values extracted from the different parametrizations for the parton distribution functions. We then conclude that the proportion of strange to non-strange quarks as calculated in the MCM is compatible with what the standard parametrizations for parton distributions tell us. For illustration, we also show in the dashed lines what would be $\bar{d}(x) + \bar{u}(x) - s(x) - \bar{s}(x)$ in the $SU(3)$ symmetry limit, which will be defined in Eq. (23).

The combination of parton distributions shown in Fig. 4 is useful for the computation of the factor $\kappa(3)$. Indeed, the numerator and denominator of Eq. (2) can be rewritten, as before, as sums of a perturbative ($P$) plus a non-perturbative ($NP$) contributions:

$$\int_0^1 dx [s + \bar{s}](x) = \int_0^1 dx [(s + \bar{s})^P + (s + \bar{s})^{NP}](x),$$

$$\int_0^1 dx [\bar{u} + d](x) = \int_0^1 dx [(\bar{u} + d)^P + (\bar{u} + d)^{NP}](x).$$

Subtracting (20) from the (19), dividing both sides by (20), and assuming that all the perturbative contributions cancel in the numerator we rewrite $\kappa(3)$ as:

$$\kappa(3) = 1 + \frac{\int_0^1 dx [s + \bar{s}]^{NP}(x) - \int_0^1 dx [\bar{u} + d]^{NP}(x)}{\int_0^1 dx [\bar{u} + d](x)},$$

(21)
where, as in Eq. (16), we have used the CTEQ4 parametrizations in the denominator. In the above expressions the non-perturbative quantities are calculated with the MCM. Using the parameters described before we find

$$\kappa(3) = 0.55,$$

in reasonable agreement with the value quoted by the CCFR collaboration [3].

The cloud parameters used so far give an overall good agreement with the available experimental information. However, they are not the result of a best fit, and a different set of parameters could yield good results as well. In particular, we would like to mention that our value for $g_{p\Delta^{0}\pi^+}$ is somewhat large (although still compatible with data) and, as it was argued in [15], a value about 30% smaller might be more appropriate. We repeated our calculation using $g_{p\Delta^{0}\pi^+} = \frac{22}{\sqrt{6}}$. The cut-off parameters had to be changed to $\Lambda_{oct} = 1.11 \text{ GeV}$ and $\Lambda_{dec} = 1.15 \text{ GeV}$, and the new multiplicities were calculated to be $n_{\pi N} \simeq 0.30$ and $n_{\pi\Delta} \simeq 0.19$. On the other hand, $\kappa(3) = 0.66$ with this new set of parameters, implying in less agreement between the model and the experimental data.

We now take the $SU(3)$ symmetry limit, which means in our case to make the masses equal within the multiplets\footnote{Other choices for the values of the masses in the symmetry limit would, of course, result in a different value for $\kappa(3)$, for instance. The important point is that equal masses within the multiplets, indicate a tendency to recover the $SU(3)$ symmetry.}, i.e.,

$$m_{\text{meson}}^{\text{octet}} = \frac{(m_{\pi} + m_{K})}{2},$$

$$m_{\text{baryon}}^{\text{octet}} = \frac{(m_{p} + m_{n} + m_{\Sigma} + m_{\Lambda})}{4},$$

$$m_{\text{baryon}}^{\text{decuplet}} = \frac{(m_{\Sigma^*} + m_{\Delta})}{2}. \quad (23)$$

As $\kappa(3)$ in Eq. (21) measures the amount of symmetry breaking between the strange and nonstrange quarks, it is remarkable that within our $SU(3)$ symmetry limit, we have $\kappa(3) = 0.96$, which is in good agreement with $\kappa(3) = 1$. We see, therefore, that in making the cloud $SU(3)$ symmetric, we recover the $SU(3)$ flavor symmetry in the parton distributions.

It is of capital importance to compare the $SU(3)$ symmetry limit, as defined by Eq. (23), with a similar limit in the $SU(2)$ case. Notice that to calculate the $\bar{d}(x) - \bar{\pi}(x)$ difference, we are already using a limit similar to that of Eq. (23). That is, we have
only one mass in the meson octet, $m_\pi$, only one mass in the barion octet, $m_p = m_n$, and only one mass in the barion decuplet, as only the $\Delta$ is relevant in that case. The bulk of the $\bar{d}(x) - \bar{u}(x)$ difference comes, then, from the mass difference between the octet and decuplet barion masses. We have checked that when $m_p \sim m_\Delta$, $\kappa(2) \sim 1$. For the $\bar{d}(x) + \bar{u}(x) - s(x) - \bar{s}(x)$ difference, however, the important contribution comes from the mass differences inside the octet and decuplet states.

2.2 The Sigma

For the $\Sigma^+$ baryon we consider the following expansion:

$$|\Sigma^+\rangle = Z \left[ |\Sigma^+_0\rangle + |\Sigma^+\pi^0\rangle + |\Sigma^0\pi^+\rangle + |\Lambda^0\pi^+\rangle + |pK^0\rangle + |\Xi^0K^+\rangle + |\Delta^{++}K^-\rangle + |\Delta^{+}\Xi^0\rangle + |\Sigma^{*+}\pi^0\rangle + |\Sigma^{*0}\pi^+\rangle + |\Xi^{*0}\Xi^0\rangle \right].$$

We included the $|\Xi^0K^+\rangle$ and the decuplet states in the second line of Eq. (24). These states were not considered in [7], and the authors of Ref. [9] considered only the two lowest lying decuplet states ($\Sigma^{*+}\pi^0, \Sigma^{*0}\pi^+$). It will be seen here that the decuplet states play an important role in the $x$ dependence of the parton distributions, in spite of their large masses.

The parton distributions in the $\Sigma^+$ sea can be straightforwardly computed through Eqs. (5)-(11), where the relevant replacements of masses and couplings have to be made. Following the steps of subsection 2.1, we take the couplings according to the $SU(3)$ relations [17]. Hence, for the octet coupling constants we have:

| $g_{\pi^+\Lambda\Sigma^+}$ | $\frac{2}{\sqrt{3}} 2\alpha_D g_{p\pi^0p}$ |
| $g_{K^+\Sigma^+\Xi^0}$ | $-g_{p\pi^0p}$ |
| $g_{\Sigma^+\Sigma^+\pi^0}$ | $2(1 - \alpha_D)g_{p\pi^0p}$ |
| $g_{pK^0\Sigma^+}$ | $\sqrt{2}(2\alpha_D - 1)g_{p\pi^0p}$ |
| $g_{\Sigma^+\pi^+\Sigma^0}$ | $2(1 - \alpha_D)g_{p\pi^0p}$ |

**Table III:** $\Sigma^+$ Octet coupling constants.

while for the decuplet couplings we have:
Table IV: $\Sigma^+$ Decuplet coupling constants.

| $g_{\Sigma^+\Delta^+K^0}$ | $g_{p\Delta^0\pi^+}$ |
|---------------------------|------------------------|
| $g_{\Sigma^+\Delta^+K^-}$ | $\sqrt{3} g_{p\Delta^0\pi^+}$ |
| $g_{\Sigma^+\Xi^0K^+}$   | $g_{p\Delta^0\pi^+}$    |
| $g_{\Sigma^+\Sigma^0\pi^+}$ | $-\frac{1}{\sqrt{2}} g_{p\Delta^0\pi^+}$ |
| $g_{\Sigma^+\Sigma^0\pi^0}$ | $-\frac{1}{\sqrt{2}} g_{p\Delta^0\pi^+}$ |

For the cut-off parameters, we will use the same values as given by Eq. (13).

In Fig. 5 we show the separate contributions from the octet and decuplet states for $x(d(x) - \pi(x))$ (5a), $x(\overline{d}(x) - \overline{\pi}(x))$ (5b), $x(\overline{\pi}(x) - \overline{\pi}(x))$ (5c). The total distributions are shown in the Fig. 5d, and they should be compared with Fig. 4 of Ref. [7]. We agree qualitatively with them. Quantitative changes are noticeable, and they happen because of the inclusion of the decuplet states which play a significant role, as seen in Figs. 5b and 5c. The fact that $x(d(x) - \pi(x)) > x(\overline{u}(x) - \overline{\pi}(x))$, was interpreted in [7, 9] as a violation of $SU(3)$ charge symmetry, and this really seems to be the case. Even more indicative of this breaking is the direct comparison of $x(d(x) - \pi(x))$ in the proton (dotted line) with $x(\overline{s}(x) - \overline{\pi}(x))$ in the $\Sigma^+$ (dot-dashed line), shown in Fig. 6. A huge discrepancy is seen between the two curves, a result in complete disagreement with naive expectations. As in the quark model the $\Sigma^+$ is a proton with the $d$ quark replaced by a $s$ quark, naively one would think that $x(d(x) - \pi(x))$ in the proton is equal to $x(\overline{s}(x) - \overline{\pi}(x))$ in the $\Sigma^+$.

As we saw in section 2.1, the PB effect is important in describing the $x$ dependence of the light quark sea asymmetry. From the point of view of Fermi statistics, the same effect should be present in the $\Sigma^+$, with the $s$ quark here playing the role of the $d$ quark in the proton. Because of the mass of the $s$ quark, the $x$ dependence of the PB in the $\Sigma^+$ may not be exactly the same as in the proton. However, to exemplify the size of the corrections from PB, we also plot in Fig. 6 the distributions including the effect of the PB given by Eq. (15). The solid line is for $x(d(x) - \pi(x))$ in the proton, and the dashed line is for $x(\overline{s}(x) - \overline{\pi}(x))$ in the $\Sigma^+$.

It seems also appropriate to extend the comparisons to $d(x) - \overline{d}(x)$ in the $\Sigma^+$, and to $s(x) - \overline{s}(x)$ in the proton. We show the $d(x) - \overline{d}(x)$ in Fig. 7, where the decuplet and octet contributions are shown separately. In Fig. 8 we show both differences and we see clearly the discrepancy between them, which is again an evidence of $SU(3)$ charge symmetry breaking. It is remarkable, however, that besides the small mass of the $d$ quark,
the $d(x) - d(x)$ asymmetry in the $\Sigma^+$ is much larger than the $s(x) - s(x)$ asymmetry in the proton.

Finally, in order to compare the $SU(3)$ flavor breaking in sea parton distributions in the $\Sigma^+$ with the proton, we compute $\kappa_3$ defined in Eq. (21). The denominator in Eq. (21) is governed by the large perturbative contributions and is only slightly affected by the cloud component. It is therefore reasonable to assume that it is the same for the proton and for the $\Sigma^+$. In the numerator we have approximated $\int dxx[s(x) + \bar{s}(x)]$ by $\int dxx[2s(x)]$ in order to avoid uncertainties associated with $s(x)$ in the hyperon. The resulting value for $\kappa_3$ is then:

$$\kappa_3 \simeq 0.85$$

(25)

This value of $\kappa_3$ indicates a violation of $SU(3)$ flavor inside the $\Sigma^+$ which is weaker than that inside the proton, whereas Figs. 4 - 7 show a violation of the $SU(3)$ symmetry between the proton and the sigma. Both symmetries are restored in the $SU(3)$ symmetry limit of Eqs. (23), i.e., $\kappa_3 \to 1$ and the curves in the figures assume their expected behaviour, with $d_{\Sigma^+} = s_p$ and $\bar{d}_{\Sigma^+} = \bar{s}_p$.

In the context of the meson cloud model this result is not surprising. The cloud expansion of the $\Sigma^+$ involves heavier states than those appearing in the proton expansion. As a consequence, the whole $\Sigma^+$ cloud will be suppressed with respect to the proton cloud. Indeed, looking at the multiplicities we observe that the probabilities associated with the hyperon states are typically one order of magnitude smaller than those associated with the proton states. Moreover, the strange states inside the proton are heavier and suppressed with respect to non-strange states, and therefore we expect (and really observe) $d > u > s$. Neglecting Pauli blocking effects, (which would slightly inhibit the $\bar{s}$ production in comparison with the $\bar{d}$ production in the $\Sigma^+$) we would expect the same behaviour for the $\Sigma^+$ and this is exactly what we find. Quantitatively, the suppression of $s$ in $\Sigma^+$ (with respect to $\bar{d}$ or $\bar{u}$), happens because all the states in the cloud contain strangeness and are nearly equally suppressed. In the proton the suppression of $\bar{s}$ (always with respect to $\bar{d}$ or $\bar{u}$) is more pronounced because of the mass difference between strange and non-strange cloud states.
3 Conclusions

In this work we have applied to meson cloud model to study the non-perturbative aspects of parton distributions, giving special emphasis to the strange sector. We have adjusted the cloud cut-off parameters to reproduce the E866 data on $\bar{d}(x) - \bar{u}(x)$ and $\bar{d}(x)/\bar{u}(x)$. In this procedure the choices were not completely free. Instead, the cut-off values had to be consistent with previous analyses of other experimental information \cite{16}. Having fixed the parameters we moved to the strange sector. In this sense, the results for the strange-anti-strange asymmetry and for $\bar{u} + \bar{d} - s - \bar{s}$ can be considered as predictions. They are consistent with data. Finally we have taken the $SU(3)$ limit in the meson cloud and found out that, in this limit, the parton distributions become $SU(3)$ flavor symmetric, i.e., $\kappa \to 1$. We have thus presented additional experimental confirmation of the MCM. Moreover we have concluded that the meson cloud is responsible for the $SU(3)$ flavor breaking in parton distributions.
