A total of 156 Shiga-like toxin producing Escherichia coli (STEC) were isolated from fecal samples of Korean native (100/568, 18%) and Holstein dairy cattle (56/524, 11%) in Korea between September 2010 and July 2011. Fifty-two STEC isolates (33%) harbored both of shiga toxin 1 (stx1) and shiga toxin 2 (stx2) genes encoding enterohemolysin (EhxA) and autoagglutinating adhesion (Saa) were detected by PCR in 83 (53%) and 65 (42%) isolates, respectively. By serotyping, six STEC from native cattle and four STEC from dairy cattle were identified as O-serotypes (O26, O111, O104, and O157) that can cause human disease. Multilocus sequence typing and pulsed-field gel electrophoresis patterns highlighted the genetic diversity of the STEC strains and difference between strains collected during different years. Antimicrobial susceptibility tests showed that the multidrug resistance rate increased from 12% in 2010 to 42% in 2011. Differences between isolates collected in 2010 and 2011 may have resulted from seasonal variations or large-scale slaughtering in Korea performed to control a foot and mouth disease outbreak that occurred in early 2011. However, continuous epidemiologic studies will be needed to understand mechanisms. More public health efforts are required to minimize STEC infection transmitted via dairy products and the prevalence of these bacteria in dairy cattle.

Keywords: cattle, Escherichia coli, multidrug resistance, serotyping, Shiga toxin
Table 1. Prevalence of Shiga toxin-producing Escherichia (E.) coli (STEC) isolated from native and dairy cattle in Korea during 2010 and 2011

| Region   | Species | Number of samples (farms) | Number of STEC isolates | Number of samples (farms) | Number of STEC isolates | Number of samples (farms) | Number of STEC isolates | Number of samples (farms) | Number of STEC isolates |

and the plate was left undisturbed at room temperature for respectively. The contents of each well were mixed well added to each well in the first, second, and third column, the test latex thoroughly, the tubes were kept in a 50°C water bath for 1 min and 2. Toxin extraction was performed for 30 min at 37°C with occasional shaking. After extraction, the culture was centrifuged at 1,200 × g for 20 min at 4°C and the supernatant was used as a test sample. Twenty-five μL of diluents, latex and control reagent, were dispensed into each well of a V-bottom microplate (Sigma-Aldrich), and 25 μL of test sample supernatant were added to the first well in each column. Two-fold dilutions were made down into each well of a V-bottom microplate (Sigma-Aldrich), μL of diluents, latex and control reagent, were dispensed into each well of a V-bottom microplate (Sigma-Aldrich), and 25 μL of test sample supernatant were added to the first well in each column. Two-fold dilutions were made down each column, up to and including row 7. Twenty-five μL of the test latex stx1 and 2 as well as the latex control were added to each well in the first, second, and third column, respectively. The contents of each well were mixed well and the plate was left undisturbed at room temperature for 20 ~ 24 h. Samples in the wells showing agglutination were classified as Stx-positive.

Serotyping

Determination of the O-antigen was carried out with heat-inactivated E. coli isolates using the slide agglutination method. A certain amount of bacterial growth was suspended in 3 mL 0.85% saline and heat to 100°C for 1 h. The suspension was pelleted at 900 × g for 20 min and a supernatant was discarded. The precipitant was then suspended with 0.5 mL 0.85% saline and used as antigenic suspension. Antigenic suspension and a drop each of polyvalent serum (Denka Seiken, Japan) were mixed and tilted back and forth for 1 min on the slide glass. Only strong agglutination observed within 1 min in the reaction with each serum was regarded as positive. Positive samples were then tested with each monovalent serum consisting of the polyvalent serum. The mixture of 0.85% saline and serum was used as a negative control.

Determination of the H-antigen was carried out using the test tube method with the bacteria cultured in liquid media. E. coli isolates passed through the semi-liquid media with a Cragie’s tube 3 ~ 5 times may be used for inoculation of the preparatory culture in the liquid medium. Then, a cell suspension was prepared by culturing in the liquid medium at 37°C overnight and adding an equal amount of 0.85% saline containing 1 w/v% formalin. Three drops of each H-antisera and 0.5 mL of the cell suspension were added into the each tubes. A tube that did not contain the antisera was regarded as a negative control. After mixing thoroughly, the tubes were kept in a 50°C water bath for 1 h. Agglutination was observed in positive samples.

MLST

MLST was performed according to E. coli MLST scheme whose databases are managed by University College Cork (Ireland). Seven housekeeping genes (adk, fumC, gyrB, ics, mdh, purA, and recA) were amplified and the PCR products were sequenced to confirm the sequence type (ST). PCR protocol is that 2 min at 95°C, 30 cycles of 1 min at 95°C, 1 min at annealing temp, 2 min at 72°C followed by 5 min at 72°C. The PCR reaction contains 50 ng of chromosomal DNA, 20 pmol of each primer, 200 umol (10 μL of a 2 mM solution) of the dNTPs, 10 μL of 10 × PCR buffer, 5 units of Taq polymerase and water to 100 μL. Allelic profile of the reference E. coli strain is filed as GenBank Accession No. U00096.

PFGE

PFGE was performed to genetically compare the STEC isolates. In brief, bacterial cells from an overnight culture in 3 mL Tryptic Soy Broth (Becton, Dickinson and Company) were pelleted at 42,511 × g for 5 min. The pelleted cells were embedded in 1% SeaKem Gold agarose (Lonza, USA) plugs and lysed by proteinase K (Sigma-Aldrich). Lysed plugs were then digested for 24 h with 40 U of XbaI (New England BioLabs, USA) at 37°C water bath. Digested plugs were then placed on 1% SeaKem Glod agarose and electrophoresis was carried out at 6.0 V/cm for 19 h with an initial switch time value of 2.16 sec and final switch time of 54.17 sec in 0.5× Tris-Brate-EDTA (TBE) buffer at 14°C [30]. PFGE patterns were analyzed using Bionumerics software (ver. 6.5; Applied Maths, USA). The degree of similarity was calculated using the unweighted pair group method with averaging (UPGMA) based on Dice similarity coefficient with 2% of tolerance. More than three isolates with over 85% similarity were considered to be one cluster group.

Antimicrobial susceptibility test

A disk diffusion test was performed and verified by an agar dilution test according to the Clinical and Laboratory Standards Institute (CLSI) guidelines [5,6] with the following antibiotic disks (Becton, Dickinson and Company): carbenicillin (CB, 100 μg), cefazolin (CZ, 30 μg), amoxicillin/clavulanate (AMC, 20/10 μg), ampicillin (P, 10 μg), imipenem (IPM, 10 μg), chloramphenicol (C, 30 μg), tetracycline (TE, 30 μg), gentamicin (GM, 10 μg), amikacin (AN, 30 μg), streptomycin (S, 10 μg), neomycin (N, 30 μg), ciprofloxacin (C, 5 μg), and nalidixic acid (NA, 30 μg). Thirteen antibiotics belonging to different antimicrobial classes were tested using BD BBL Sensi-Disks (Becton, Dickinson and Company): carbenicillin, cefazolin, amoxicillin/clavulanate, ampicillin, imipenem, chloramphenicol, tetracycline, gentamicin,
amikacin, streptomycin, neomycin, ciprofloxacin, and nalidixic acid. Colistin resistance was tested with the broth dilution technique. Multidrug-resistant (MDR) *E. coli* were defined as bacteria that were resistant to at least three different classes of antimicrobials.

### Statistical analysis

Statistical differences between STEC strains isolated from native and dairy cattle were analyzed using a Chi-square test with PASW Statistics 18 (SPSS, USA). At the 95% confidence level, *p* values < 0.05 were considered statistically significant.

### Results

#### Prevalence of STEC

A total of 1,092 fecal swab samples were collected in the present study. In 2010 and 2011, 192 and 376 samples were collected from native cattle, respectively, while 122 and 402 samples, respectively, were obtained from dairy cattle. *E. coli* isolates were classified as STEC when *stx* 1 or *stx* 2 genes were detected by multiplex PCR. STEC colonization rates of the native and dairy cows were 17.61% and 10.69%, respectively. The overall prevalence of STEC ranged from 20.38% (64/314) in 2010 to 11.82% (92/778) in 2011. STEC colonization rates in native cattle decreased significantly during the study period from 29.68% in 2010 to 11.43% in 2011 (*p* < 0.001). On the other hand, the colonization rates of dairy cows increased from 5.73% in 2010 to 12.19% in 2011 (*p* < 0.05). Evaluation of regional distribution showed that Gyeonggi and Gangwon had higher prevalence rates than other parts of the country regardless of the species and year except for dairy cattle in Gangwon surveyed in 2010 (Table 1).

#### Detection of *stx* 1, *stx* 2, and other virulence genes

The number of STEC isolates that carried only *stx* 2 and not *stx* 1 was highest in 2010 (Table 2). In contrast, the *stx* 1+/*stx* 2− STEC rates increased among both native and dairy cows in 2011 (Table 2). *saa* and *ehxA* genes were generally prevalent. *saa*, *ehxA*, and *eaeA* genes were detected more frequently in isolates from dairy cattle than in those from native bovines (Table 3). From 2010 to 2011, there was little difference in the prevalence of all virulence genes in native cows. On the other hand, prevalence of the *saa* gene increased significantly in dairy cows while prevalence of the *eaeA* gene decreased. This is because the increased number of STEC isolates in 2011 compared to that obtained in 2010 enhanced the STEC population overall, and made the results of virulence gene survey in dairy cattle more reliable.

#### Detection of SLT production

A correlation between the *stx* genotype and phenotype was observed in this study. Most STEC isolates bearing an *stx* gene produced the corresponding toxin type that was detected with an RPLA test. The phenotypes of one (6%) *stx* 1+/*stx* 2− STEC isolate, 11 (13%) *stx* 1−/stx* 2+ isolates, and four (8%) *stx* 1+/*stx* 2+ isolates could not be determined (Table 2).

#### Serotyping

In the present investigation, we focused on serotypes that have the greatest impact on public health and safety. In native cattle, STEC with three O26 isolates (5%), one O111 isolate (2%), and two O157 isolates (4%) serotypes were identified. All of these STEC isolates were obtained in 2010. From dairy cows, STEC with one O104 isolate (2%) and three O157 isolates (6%) serotypes were identified in 2011 (Table 4). Two stains of O8:H19 were obtained from native cattle in 2010 and one strain each of O8:H19 and O8:H21 was recovered from dairy cows in 2011. These serotypes have been associated with HUS in other countries [21]. No STEC with O157:H7 or O104:H4 serotypes were isolated in the present study.

#### MLST

MLST analysis of isolates collected in 2010 revealed the

Table 4. Frequency of different STEC with the O-serotype from native and dairy cattle isolated between 2010 and 2011

| Species | Year | O-serotype (number of strains) |
|---------|------|--------------------------------|
| NC      | 2010 | 6 (2)*, 8 (4), 15 (1), 26 (3), 111 (1), 125 (1), 146 (5)*, 157 (2), 112ac (2), NT (36) |
|         | 2011 | 1 (1), 6 (1)*, 44 (1), 146 (1)*, NT (39) |
| DC      | 2010 | NT (7) |
|         | 2011 | 8 (3), 15 (1), 104 (1), 153 (1), 157 (3), 28ac (1), NT (39) |

*O-serotypes were detected in both 2010 and 2011. NT: non-typtable with antisera.

The presence of 45 different STs including 34 newly designated STs. The most commonly detected ST among native cows and dairy cows was ST223. The most prevalent ST was ST10 (5/64, 7.81%) followed by ST2101 (4/64, 6.25%) and ST297 (3/64, 4.69%). On the other hand, in 2011, due to increased STEC isolations of dairy cattle, various 32 STs were identified and different from six STs (except for ST223) among total seven STs from dairy cattle in 2010 samples. The most frequent ST was ST2385, a newly identified type that accounted for 22.45% (11/49); the remaining 22 STs accounted for 2∼8%. For the native cattle strains, ST10 was predominant (25.58%, 11/43) and 19 remaining STs accounted for 2∼9% (Table 5).

**PFGE**

XbaI-digested DNA fragments from 156 STEC isolates revealed the presence of 38 genetically related groups with 85% similarity (Fig. 1). Individual PFGE patterns contained between 17 and 25 discernible DNA fragments ranging from 50 to 800 kb in size. There was no tendency for a specific group to be dominant throughout the country. Only seven groups (G6, G14, G23, G24, G28, G29, and G34) contained STEC isolates acquired in both 2010 and 2011. All other groups consisted of STEC isolates obtained during only one year (either 2010 or 2011). No differences in PFGE patterns were observed between dairy and native cows similar to the MLST findings, but PFGE patterns seemed to be affected by region. Eleven (84.6%) out of 13 groups of PFGE patterns were identified in isolates acquired in 2010 from the same regions. Seven (38.9%) out of 18 groups were observed among STEC collected in 2011 from the same areas. The remaining groups contained STEC isolates from more than two different regions in which only Gyeonggi overlapped the various other areas except for Jeju.

**Antimicrobial susceptibility test**

Results of antimicrobial susceptibility tests for isolates from 2010 and 2011 indicated that resistance to tetracycline, streptomycin, ampicillin, and carbenicillin were most frequent. A marked increase in antibiotic resistance rates was found for isolates obtained in 2011 (Fig. 2). Antibiotic resistance rates of STEC isolates that were resistant to more than one drug were 14.3% for dairy cows and 45.6% for native cattle in 2010, but grew the rate rapidly in 2011 (73.5% in dairy cows and 79.1% in native cattle). The rate of MDR (resistance to more than three antibiotics) also increased greatly over time from 14.29% to 51.16% in dairy cows and 12.28% to 28.57% in native cattle. Resistance rates against carbenicillin, amoxicillin/clavulanate, ampicillin, colistin, neomycin, amikacin, and streptomycin also significantly increased between 2010...
Table 5. Multilocus sequence typing analysis of STEC isolates recovered from native and dairy cattle in 2010 and 2011

| Species/Year | NC           | DC           | Total number of isolates (%) |

STEC were divided into six groups according to sequence typing (STs). G1: overlapping STs between 2010 and 2011, G2: STs found only among isolates from native cattle collected in 2010, G3: STs found only among isolates from dairy cattle obtained in 2010, G4: overlapping STs between native and dairy cattle in 2011, G5: STs discovered only among isolates from native cattle in 2011, G6: STs discovered only among isolates from dairy cattle in 2011. Sequence type of one STEC isolate obtained in 2010 could not be identified. *New alleles and STs.

and 2011. The analytical results of carbenicillin, amoxicillin/clavulanate, ampicillin, and neomycin were \( p < 0.001 \) and colistin, amikacin, and streptomycin were \( p < 0.05 \) that means the results were considered statistically significant.

**Discussion**

In this large-scale, nationwide study, the overall prevalence of STEC isolated from rectal swabs of healthy adult cows was 20.38% in 2010 and 11.82% in 2011. In previous studies, the STEC prevalence in Korea was 10.5% for diarrhea samples from calves [19] and 9.5% for samples from cattle feces [4]. These rates are lower than ours in 2010 but similar to those in 2011. The prevalence of STEC in cattle has also been reported in several studies from different countries. Compared to our results, the STEC prevalence for Vietnam (26%), Japan (37.5%), France (34%), and Spain (35%) were reported to be higher [3,11,29,37] and that for Germany (17.0%) was similar [20]. The STEC prevalence for the United States (8.4%) was lower than the prevalence found in the present study.
Fig. 1. Characteristics of 38 groups established based on PFGE (XbaI) patterns of 156 STEC isolated from native and dairy cattle in six regions of Korea between 2010 and 2011. A, Gyeonggi; B, Chungcheong; C, Jeolla; D, Gyeongsang; E, Gangwon; F, Jeju. *MLST cplx is the clonal complex of multilocus sequence typing.
Korea. Consequently, many wild animals inhabit this region and have many opportunities to come into contact with cows. Wildlife sharing the surrounding farmland with cattle could potentially shed STEC along with the cattle, thereby contributing to the transmission of STEC to livestock herds [8].

PCR results demonstrated that stx1−/stx2+ was the predominant type among the STEC isolates from both kinds of cows in 2010. This result coincides with those from a previous report [3] showing that STEC harboring the stx2 gene is prevalent among adult cows. However, the number of stx1−/stx2+ STEC isolates collected in 2011 decreased while the number of stx1+/stx2+ STEC isolates increased. This may be due to seasonal variations during the sampling period or because of an FMD outbreak that occurred between the two sampling periods. These factors could have altered the populations of STEC organisms but further study is necessary.

An immunoassay for the in vitro detection of Shiga (Vero) toxins stx1 and 2 (VTEC-Screen; Seiken) was performed to compare with the results from the stx gene-specific PCR to detect STEC. Although PCR is suitable for the general identification of STEC, the RPLA assay has also a high degree of specificity for detecting Stx-positive stool samples. The RPLA assay evaluates the expression of stx genes rather than just checking for the existence of these genes in the bacteria chromosomal DNA [2]. The STEC-specific screen detected 95 (95%) out of 100 STEC isolates from dairy cows (Table 2). Sensitivity of the RPLA was less than that of PCR, which was similar to published results, and there were no false positives [2]. When the data were analyzed according to toxin type, there was a false negative stx1 sample and 15 false negative stx2 samples. Beutin et al. [2] noted that some stx2 and stx2 variant strains (i.e., Stx2-Ount and stx2e/stx2ev) produce only small amounts of toxin that are insufficient for detection by the RPLA assay. Therefore, additional experiments are required to determine whether suspected samples produce toxins. Additionally, there may be issues related to cross reactivity when performing the assay.

Pathogenic STEC strains not only produce Shiga toxins but can also manufacture other virulence factors that may cause more severe human illnesses [13]. The present study focused on intimin, auto-agglutinating adhesion, and plasmid-encoded enterohemolysin. These factors of STEC, which are considered to be highly virulent in humans, are necessary to generate the attaching and effacing lesions (A/E lesions) that enable adherence to enterocytes. Intimin encoded by eaeA, which is included in the “pathogenicity island” known as the locus for enterocyte effacement (LEE), is involved in the production of A/E lesions [40]. Therefore, the LEE, which is commonly identified by detection of the eaeA gene, appears to confer enhanced
virulence. However, the LEE is not essential for pathogenesis because many cases of severe STEC disease, including HUS and thrombotic thrombocytopenic purpura, were caused by LEE-negative strains [26]. Paton suggested that *saa* is a marker of LEE-negative STEC used to designate an ill-defined subset similar to *eaeA* in LEE-positive STEC capable of causing life-threatening disease in humans [25]. In the present study, none of the STEC isolates possessed both *eaeA* and *saa*, and *saa* (41%) was detected more frequently than *eaeA* (12%) regardless of the collection period or species. This finding indicates that LEE-negative STEC strains are more prevalent than LEE-positive STEC in Korea.

It was previously shown that there is a correlation between the presence of *saa* and *ehxA* in certain STEC strains [25]. This result is in agreement with our finding. All of the isolates positive for *saa* were also positive for *ehxA* while 16 isolates positive for *ehxA* were negative for *saa*. Among the 16 isolates positive for *ehxA*, 13 were also positive for *eaeA*. Therefore, at least 13 *ehxA*-positive isolates were among the LEE-positive STEC strains. Considering the possible correlation between *saa* and *ehxA*, a plasmid-encoded repeats in toxin (RTX) toxin that carries the *ehxA* gene in the LEE-positive and -negative STEC strains is different [25]. According to the prevalence of the three virulence factors, more severe illness in humans is associated with STEC infection in dairy cattle since all virulence genes were found more frequently in isolates from dairy cows than native cows.

Detection of major STEC serotypes related to severe human diseases was performed. Only a few strains were found to possess the O26, O104, O111, and O157 serotypes. Among STEC obtained in 2010, three (5%) O26 isolates, one (2%) O111 isolate, and two (4%) O157 isolates were detected only in samples from native cattle. In 2011, one (2%) O104 isolate and three (6%) O157 isolates were detected only in samples from dairy cattle. In a previous study in Korea [4], the same O serotypes were found but the detection rates were different (O157, 42%; O26, 42%; and O111, 1%). This difference may be due to different sampling methods and animal species. Our results were similar with those from a study conducted in Japan (O157, 1.1%; O26, 9.8%; O111, 1.1%; O104, 2.2%) [17]. Along with the data for the virulence factor assay, we should take notice of the recent increases in the number of strains with disease-associated serotypes in dairy cattle.

STEC isolates acquired in 2010 and 2011 had different STs and several new STs were identified. This is because the majority of available databases contain information for *E. coli* strains from Europe, North America, Africa, and Asia [28] but only a few strains from Korea are included. In a previous investigation performed in Korea [18], MLST results for three pathogenic *E. coli* isolates showed that one strain was ST101 while the others had novel STs (ST1815 and ST1820). In the present study, we performed MLST on 156 STEC isolates from a large-scale sampling of healthy cows in Korea and discovered new STs. There was only one overlapping ST (ST223) between the native and dairy cows in 2010 but 11 STs overlapped in 2011. This finding could mean there was no preferable ST for the two breeds of cattle. As far as the regional aspect of STs, ST10 was detected throughout the country except for in the F region for over 2 years. However, it appeared only in the A and E regions narrowly in 2010 and was not the most frequently detected ST in 2011, it is reasonable to conclude that there is presently no predominant ST throughout Korea. Additionally, most identified STs were different from in 2010 with in 2011. This result could be due to seasonal variations or an FMD outbreak occurring over 2 years ago. We assume that seasonal differences including ambient temperature, rainfall, and other seasonally driven factors such as insect populations affect changes in STEC strain pools [1]. Another assumption is that the national large-scale slaughtering and burying of cattle to control the transmission of FMD as well as environmental changes on farms such as reinforcement of sanitation control and different raising systems prevented continuous infection with STEC strains and selected for other STEC strains.

In the present study, DNA from 156 STEC isolates was digested with *XbaI* and 38 clusters with 85% similarity were identified based on the PFGE patterns generated. There was no specific STEC isolated across the country in the clusters. Out of the 38 groups, only five (G6, G14, G23, G24, G28, G29, and G34; 18.4%) contained STEC strains collected during both 2010 and 2011. The other groups included STEC strains isolated in either 2010 or 2011. The low degree of similarity between STEC obtained in 2010 and strains acquired in 2011 is indicative of low genetic relatedness. This finding agrees with the MLST result demonstrating that there was not continuous infection by STEC strains all year round but PFGE profiles of infected STEC strains had changed.

In addition, no preference for STEC strain was found in a specific kind of cattle, but regional and spatial effects were important for the PFGE grouping. STEC from the same farm or region was mainly grouped together in the present study. Cobbold and Desmarchelier [7] previously suggested that contact between the animals and various materials, such as drinking and feeding troughs, enables STEC to be disseminated by horizontal transmission. Of all the regions, STEC patterns for isolates from Gyeonggi overlapped with those of STEC from other regions. This is because there is vigorous exchange of STEC between Gyeonggi and other regions. The current study used two methods to evaluate STEC epidemiology but could not compare the PFGE and MLST findings due to a number of new STs. However, both PFGE and MLST findings can be meaningful for assessing genetic relatedness among the
STEC strains on a large national scale.

Results of the antimicrobial susceptibility tests in this investigation were similar to those from studies conducted in other countries demonstrating that streptomycin and tetracycline resistance were prevalent among isolates from cattle [21,23]. Furthermore, an earlier study performed in Korea indicated that most STEC isolates were resistant to carbenicillin and ampicillin [4,19]. Tetracycline, streptomycin, ampicillin, and carbenicillin resistance were frequent regardless of species in the current investigation. The prevalence of resistance to these antibiotics except for tetracycline increased in 2011. It is worth noting that the percentage of antibiotic resistance to not only one drug but also multiple drugs increased considerably in 2011 compared to the previous year. It was assumed that this result was also due to seasonal variations or FMD infection. Since antimicrobials are administered more frequently in summer than autumn, STEC isolates collected during the summer sampling in 2011 were more resistant to most antibiotics. To prevent secondary bacterial infection following viral diseases, many kinds of antibiotics might be excessively and indiscriminately administered. This would increase residual antibiotic levels in livestock and lead to the emergence of drug-resistant bacteria [36]. The increasing rate of antimicrobial resistance can cause public health problems. Therefore, continuous epidemiological evaluation will be needed.

To reduce the risk of STEC infection and improve food safety, we studied the characteristics of STEC isolated from farms in different parts of Korea. We discovered that the STEC pool had changed due to seasonal variations or FMD infection between 2010 and 2011. In addition, the risk of STEC infection increased more in dairy cows than native cattle, and the antibiotic resistance of STEC isolates also increased over the 2-year sampling period. This result might be attributed to seasonal variations during the sampling period or to FMD outbreaks that occurred between 2010 and 2011. Our findings indicated that attention should be paid to the STEC distribution among dairy cattle. In addition, continuous epidemiological studies evaluating the factors influencing the changes in antibiotic resistance and the STEC pool over the past 2 years are needed.

Acknowledgments

This study was supported by the Animal and Plant Quarantine Agency (0468-20110013), and Institute of Planning and Evaluation for Technology in Food, Agriculture, Forestry, and Fisheries (IPET 311001-03-1-HD120), Korea. Additional support was provided by the Research Institute of Veterinary Science, Department of Veterinary Microbiology, College of Veterinary Medicine, and the BK21 Program for Veterinary Science, Seoul National University, Korea.
