ABSTRACT

Context. The International Gamma-Ray Astrophysics Laboratory (INTEGRAL) is discovering a large number of new hard X-ray sources, many of them being HMXBs. The identification and spectral characterization of their optical/infrared counterparts is a necessary step to undertake detailed study of these systems. In particular, the determination of the spectral type is crucial in the case of the new class of Supergiant Fast X-ray Transients (SFXTs), which show X-ray properties common to other objects.

Aims. Our goal is to perform spectral analysis and classification of proposed counterparts to HMXBs in order to characterize the system they belong to.

Methods. We used the ESO/NTT SofI spectrograph to observe proposed IR counterparts to HMXBs, obtaining $K_s$ medium resolution spectra ($R = 1320$) with a S/N $\gtrsim 100$. We classified them through comparison with published atlases.

Results. We were able to spectrally classify the six sources. This allowed us to ascribe one of them to the new class of SFXTs and confirm the membership of two sources to this class. We confirmed the spectral classification, derived from optical spectroscopy, of a known system, 4U 1907-09, showing for the first time its infrared spectrum. The spectral classification was also used to estimate the distance of the sources. We compared the extinction as derived from X-ray data with effective interstellar extinction obtained from our data, discussing the absorption component due to the circumstellar environment, which we observed in four systems; in particular, intrinsic absorption seems to emerge as a typical feature of the entire class of SFXTs.

Key words. X-rays: binaries -- stars: supergiants -- accretion -- infrared: stars

1. Introduction

High Mass X-Ray Binaries (HMXBs) are systems composed of an early-type massive star and an accreting compact object. All sub-groups of HMXBs involve OB type stars and are commonly found in the galactic plane and in the Magellanic Clouds, among their OB progenitors.

The majority of the known systems are Be/X-ray Binaries (BeXRBs), consisting of a neutron star accreting matter from the circumstellar equatorial disc of a Be star. Most of them are transient, exhibiting short and bright outbursts ($L_X \sim 10^{36} - 10^{37}$ erg s$^{-1}$ in the case of Type I outbursts, generally close to the periastron passage of the neutron star; $L_X \gtrsim 10^{37}$ erg s$^{-1}$ in the case of Type II outbursts).

In the second major class of HMXBs, the Supergiant X-ray Binaries (SGXRBs), the counterpart is an early supergiant star, feeding the compact object with its radially outflowing stellar wind. As a result, the SGXRBs are, generally, persistent systems ($L_X \sim 10^{36}$ erg s$^{-1}$).

The five-year INTEGRAL data possibly reveal a different scenario. A recent subgroup has been proposed by [Negueruela et al. 2006], named Supergiant Fast X-ray Transients (SFXTs): these objects, associated with a supergiant companion, occasionally undergo a short period of X-ray activity lasting less than a day, typically a few hours [Negueruela et al. 2005], with a very different behavior from those observed in other X-ray binaries. These outbursts show very sharp rises, reaching the peak of the flare in $\lesssim 1$ hour. The decay is generally of a complex kind, with two or three further flares. The physical reason for these fast outbursts is still unknown, although theoretical speculations would connect them to some sort of discrete mass ejection from the supergiant donor (Golenetskii et al. 2003) or to wind variability (in’t Zand 2005), or to the possible presence of a second, equatorial, wind component (Sidoli et al. 2007). Due to high interstellar absorption and to the transient nature of these sources, SFXTs are difficult to detect, and in most cases, the sources had not been detected by previous missions. To date, six objects have been firmly characterized as SFXTs, but many other systems are likely candidates, and their number has grown rapidly since the launch of INTEGRAL (Winkler et al. 2003), so that they could actually constitute a major class of X-ray binaries.

Up to now, the INTEGRAL survey of the Galactic Plane and central regions has revealed the existence of more than 200 sources (Bird et al. [2007]) and Bodaghee et al. [2007] in the energy range 20–100 keV, with a position accuracy of $2 \arcmin - 3 \arcmin$, depending on count rate, position in the FOV and exposure. A large fraction of the newly discovered sources are found to be heavily obscured, displaying much larger column densities ($N_H \gtrsim 10^{23}$ cm$^{-2}$) than would be expected along the line of sight (see Kuulkers [2005]). These sources were missed by previous high-energy missions, whose onboard instruments were sensitive to a softer energy range. Moreover, optical counterparts to these obscured sources are poorly observable due to the high interstellar extinction, with $A_V$ in excess of up to...
~ 20 mag.

In this context, the recent availability of infrared spectroscopy has emerged as a strong tool to characterize these systems and, together with high-energy data, reveal the HMXB sub-class they belong to. This results in the identification of the mass transfer process of the system, with information about the intrinsic physics of the X-ray binary. The need for low energy data is particularly urgent in the case of SFXTs, which show X-ray properties common to other objects (such as RS CVs binaries and Low Mass X-ray binaries) and thus crucially require the spectral classification of their counterpart in order to be properly discerned.

In this paper we present spectral analysis and classification of six HMXBs discovered (or re-discovered) by INTEGRAL. The selected IGR sources are the following: IGR J16207–5129, IGR J16465–4507, IGR J16479–4514, AX J18410.0–0536 and IGR J19140+0951. We also included the well known system 4U 1907+0951 since the spectral classification of its counterpart has been a matter of debate in the past, and no infrared spectra have been published up to now. The first three sources are located in the direction of the Norma-arm tangent region, the fourth in the Scutum-arm tangent region, the fifth and the last one in the Sagittarius arm tangent. In the next section we describe the observations and data reduction; in Section 2 we report the obtained spectra, analyze their features and propose a classification; we calculate the interstellar hydrogen column density and estimate the distance to each source; in section 3 we discuss our results, before concluding.

Preliminary results of our data analysis for AX J1841.0–0536 and IGR J19140+0951 were published in Nespoli et al. (2007).

### 2. Observations and data analysis

We selected proposed counterparts, choosing sources observed by X-ray missions like XMM or Chandra, which can produce a very small error circle and facilitate the detection of the counterpart.

Data were obtained in visiting mode during two observing runs, in July 2006 and May 2007 respectively, at the European Southern Observatory (ESO). The employed instrument was the SofI spectrograph (Moorwood et al. 1998), on the 3.5m New Technology Telescope (NTT) at La Silla, Chile. Table I reports the observation log, including, for each spectrum, the retrieved signal-to-noise ratio (S/N).

| Source          | K mag | Start time (UT) | Exp. time (s) | S/N | IR Counterpart | Reference                        |
|-----------------|-------|-----------------|---------------|-----|----------------|----------------------------------|
| IGR J16207–5129 | 9.1   | 2006-07-14 23:19 | 600           | 100 | 2MASS J16204627-5130060 | Tommick et al. (2006)            |

| IGR J19140+0951 | 7.1   | 2006-07-14 04:46 | 360           | 130 | 2MASS J19140422+0952577 | in’t Zand et al. (2004)          |

In order to ensure accurate removal of atmospheric features from the spectra, we followed a strategy similar to that outlined by Clark & Steele (2000). At the telescope, we observed an A0 - A3 III–V standard star immediately before or after each target and a G2-3 V star once per hour in order to obtain very small differences in airmass (differences between 0.01 and 0.04 airmasses were accomplished). To compute the telluric features in the region of the H1 21 661 Å (Brackett–γ line, or Bry), which is the only non-telluric feature in the A-star spectra, we employed the observed G-star spectra divided by the solar spectrum1 properly degraded in resolution. The dispersion solution obtained for the SofI spectra was also applied and the spectra of the A star, G star and the solar one were aligned in wavelength space. A telluric spectrum for each scientific target was obtained by patching into the A-star spectrum the ratio between the G star and the solar spectrum in the Bry region (we selected the range 21 590 - 21 739 Å).

Typical integration times for standard stars were between 3 and 7 minutes.

Data reduction was performed using the IRAF2 package, following the standard procedure. We first corrected for the inter-quadrant row cross-talk, a feature that affects the SofI detector; we then applied sky subtraction; we employed dome flat-fields and extracted one dimensional spectra. Wavelength calibration was accomplished using Xenon and Neon lamp spectra. Spurious features, such as cosmic rays or bad pixels, were removed by interpolation, when necessary. The reduced spectra were normalized by dividing them by a fitted polynomial continuum. We corrected for telluric absorption, dividing each scientific spectrum by its corresponding telluric spectrum, obtained as described above. A scale and a shift factor were applied to the telluric spectrum, to best correct for the airmass difference and the possible wavelength shift; the optimum values for these parameters were obtained using an iterative procedure that minimizes the residual noise.

### 3. Results

In this section we present the results of spectral classification and analysis for each target. The field of NIR spectral classification

---

1 We used the NSO/Kitt Peak FTS solar spectrum, produced by NSF/NOAO

2 IRAF is distributed by the National Optical Astronomy Observatories which is operated by the Association of Universities for Research in Astronomy, Inc. under contract with the National Science Foundation
is still very young and the level of required S/N and resolution to perform a quantitative profile analysis are very high ($R \sim 12\,000$ and $S/N \gtrsim 250$), especially for young massive stars, as shown by Hanson et al. (2005b). The difficulty of the analysis depends on the few lines available and the relatively large uncertainty in their strength, due to their intrinsic weakness; moreover, some significant spectral regions, specifically through the 20 580 He I and the Brγ features, pose systematic complications because of the strong telluric absorption.

Under this premise, our analysis will be qualitative, based on the comparison with available NIR spectral atlases (Hanson et al. 1996, 2005a). According to our estimation, this approach implies that the resulting spectral classification is provided with an uncertainty of no more than one luminosity subclass. The spectral type is precise up to one subtype.

Some of the identified features exhibit a 10-20 Å displacement with respect to the nominal values, consistent with the instrumental resolution. Greater displacements, up to a maximum of 29 Å, are found corresponding to lines characterized by a spectral type is precise up to one subtype.

In the next section we will classify the spectra, showing the features we were able to identify, with the corresponding equivalent width. Although it was pointed out (Hanson et al. 1996) that equivalent widths may show variations between stars, we report them for completeness. The values we calculated are a priori uncertain width. Although it was pointed out (Hanson et al. 1996) that equivalent widths may show variations between stars, we report them for completeness. The values we calculated are a priori width. Although it was pointed out (Hanson et al. 1996) that equivalent widths may show variations between stars, we report them for completeness. The values we calculated are a priori

3.1. Spectral analysis and classification

3.1.1. IGR J16207–5129

The source was discovered by IBIS/ISGRI in the first Galactic Plane Survey performed by INTEGRAL (Bird et al. 2004), which measured a flux of $3.8 \pm 0.3$ mCrab in the 20–40 keV range. Instead, only the upper limit of < 4 mCrab was obtained in the 40–100 keV band. Subsequent Chandra observations allowed the identification of the optical/infrared counterpart. This was associated with USNO-B1.0 0384-0560857 = 2MASS J16204627-5130060 by Honsick et al. (2006). The power-law spectral fit provided $N_H = 3.7_{-1.2}^{+1.5} \times 10^{22}$ cm$^{-2}$ and photon index equal to 0.5$^{+0.6}_{-0.5}$, indicating an intrinsically hard source. The lower limit to the stellar temperature was estimated to be $> 18\,000$ K, revealing the presence of a very hot, massive star. From the fit of optical/IR spectral energy distributions, the distance was estimated to be between 3-10 kpc (3.9 kpc in the case of a supergiant classification). Subsequent optical spectroscopy from Massetti et al. (2006) refined the distance estimate to 4.6 kpc.

Negueruela & Schurch (2007), from optical observations, constrained the spectral type to earlier than B1.

Figure 1 shows the $K_s$ spectrum we obtained, with identified spectral features marked.

The spectrum shows no metal lines (no N II or C IV), strong He I 20 581 Å emission, He I absorption at 21 126 Å and moderately strong Brγ absorption. The atomic transitions observed are the typical of OB star spectra. The He I 20 581 Å line is a prominent feature in supergiant stars, so that it is considered an important tracer of stars with extended atmospheres. It becomes weak or even disappears in main sequence stars and it is observed in emission in B type supergiants, whereas it is in absorption in O type supergiants (Hanson et al. 1996). The He I 21 126 Å line is present in late O – early B spectra.

For what was outlined above, and by comparing the relative strengths of the identified lines with those of Hanson et al. (1996, 2005a), we estimate the spectral type of the IGR J16207–5129 counterpart to be B1 Ia. This allows us to classify the system as a SGXRB, as also inferred by Negueruela & Schurch (2007).
Fig. 2. $K_s$ spectrum for 2MASS J16463526-4507045, the infrared counterpart of IGR J16465-4507. The positions of identified spectral features are marked by solid lines.

Fig. 3. $K_s$ spectrum for 2MASS J16480656-4512068, the infrared counterpart of IGR J16479-4514. The positions of identified spectral features are marked by solid lines.

Fig. 5. $K_s$ spectrum for 2MASS J16463526-4507045, the infrared counterpart of IGR J16465-4507. The positions of identified spectral features are marked by solid lines.

3.1.3. IGR J16479–4514

The source was discovered by INTEGRAL (Molkov et al. 2003) during an outburst. The X-ray spectrum is fitted with a power law with a high-energy cut-off, with spectral index $\Gamma = 1.4$, and the column density is $N_H = 12 \times 10^{22}$ cm$^{-2}$ (Lutovinov et al. 2005).

IGR J16479–4514 showed short outbursts with very fast rises, observed in 2003 by Sguera et al. (2005). Its X-ray behavior is thus typical of SFXTs (Negueruela et al. 2006), however the lack of an optical/infrared spectral classification prevented the possibility of enrolling it in this new class of objects.

The counterpart to the source was identified by Kennea et al. (2005) through SWIFT observations.

Figure 3 shows the $K_s$ spectrum we obtained, with identified spectral features marked.

The spectrum shows He i 20 581 Å in strong absorption, well recognizable although affected by a clear telluric residual. The difference we obtained in airmasses between the telluric standard star and the target was in this case very low, equal to 0.004: we thus suppose that the poor correction of telluric absorption is due to the passage of a cirrus during the observation of the telluric standard.

We can also detect absorption at He i 21 126, a weak N iii 21 155 Å emission (which, according to Hanson et al. 2005a), could alternatively be C iii, and moderately strong Br y absorption.

We conclude that the spectrum shows the typical features of a late O supergiant, especially the presence of He i 21 126 (typical of late-O and early-B stars) in combination with He i 20 581 Å, present in supergiant stars, and seen in absorption in late-O supergiants. Through the comparison with the atlases from Hanson et al. (1996, 2005a), we estimate the spectral type to be O9.5 Iab. This result, together with those from X-ray data, allows us to affirm that the object belongs to the new class of SFXTs.

3.1.4. AX J1841.0–0536

AX J1841.0–0536 was discovered as a violently variable transient by ASCA in April 1994 (Bamba et al. 2001). The source showed multi-peaked flares with a sharp rise. Analysis of the ASCA data revealed that the source is a pulsar with $P_{\text{spin}} = 4.7$ s. The spectral fit provided a value of $N_H = 3.2 \times 10^{22}$ cm$^{-2}$ (Bamba et al. 2003). A fast outburst observed by INTEGRAL was attributed by Halpern & Gotthelf (2004) to this source.

A Chandra observation of the field revealed the counterpart to be 2MASS 18410043-0535465, a reddened star with weak H$\alpha$ in emission (Halpern et al. 2004), suggesting it was a Be star. Negueruela et al. (2006), from optical spectroscopy, proposed the star is instead a luminous B0-I type, although with
some uncertainty, classifying the system as an SFXT.

Figure 5 shows the $K_s$ spectrum we obtained, with identified spectral features marked.

The spectrum shows He I 20581 Å emission, accompanied by a spurious feature, possibly due to poor telluric component removal; we observe absorption at He I 21126, a weak N II (C m) 21155 Å emission; moreover, there is moderately strong Brγ absorption. The side features of the Brγ absorption profile are probably due to poor telluric correction, but they do not prevent us from measuring the equivalent width.

The observed transitions are typical of an early supergiant, and by comparison with the atlases from Hanson et al. [1996, 2005a], we can conclude that the star is of B1 Ib type. Together with X-ray properties, this NIR spectral classification allows us to confirm the nature of the system as an SFXT.

### 3.1.5. 4U 1907+09

The wind-accreting system 4U 1907+09 ([Giacconi et al., 1971]) is a known HMXB consisting of a neutron star in an eccentric ($e = 0.28$) 8.3753 day orbit around its companion, which has been optically identified as a highly reddened star ([Schwartz et al., 1980]). The spectral classification of the counterpart to 4U 1907+09 has been matter of debate. The presence of X-ray flaring seen twice per neutron star orbit ([Marshall & Ricketts, 1980]) had led some authors (e.g., [Makishima et al., 1984], [Cook & Page, 1987], [Iye, 1986]) to the hypothesis of a Be star companion. However, this classification would require a distance of <1.5 kpc, which is in contradiction to the significant interstellar extinction measured in optical observations by [van Kerkwijk et al., 1989], who also classified the counterpart as a B supergiant. Using interstellar atomic lines of Na I and K I, [Cox et al., 2005] set a lower limit of 5 kpc for the distance and proposed that the stellar companion is instead an O8-O9 Ia supergiant with an $e = 0.28$ 8.3753 day orbit around its companion, which has been optically identified as a highly reddened star ([Schwartz et al., 1980]).

Figure 6 shows the $K_s$ spectrum we obtained, with identified spectral features marked.

The spectrum shows He I absorption both at 20580 Å and at 21126 Å, a weak N II (or C III) emission line at 21155 Å and strong Brγ absorption (EW < 4 Å), the typical features of an early supergiant. The presence of He I 20580 in absorption strongly constrains the spectral type to a late O star. By comparison with the atlases from Hanson et al. [1996, 2005a], we conclude that the star is an O9.5 Iab. We thus confirm and refine the previous spectral classification.

### 3.1.6. IGR J19140+0951

The INTEGRAL discovery of this source was reported by [Hannikainen et al., 2003]. Observations with the Rossi X-Ray Timing Explorer (RXTE) revealed a rather hard spectrum, fitted with a power law of photon index 1.6 and an absorption column density of $N_H = 6 \times 10^{22}$ cm$^{-2}$ ([Swank & Markwardt, 2003]). Timing analysis of the RXTE All-Sky Monitor (ASM) data showed an X-ray period of 13.55 days ([Corbet et al., 2004]). [Hannikainen et al., 2004] presented high energy spectral analysis of the period of the discovery, concluding that the source manifests two distinct spectral behaviors, the first showing a thermal component in the soft X-ray and hard X-ray tail, the second being harder and possibly originating from thermal Comptonization. This second, low-luminosity, behavior was confirmed to be the preferred state of the source ([Rodriguez et al., 2005]).

The optical/infrared counterpart to IGR J19140+0951 was identified by [van der Zand et al., 2006] from Chandra accurate position determination, as the heavily reddened 2MASS J19140422+0952577.

Figure 7 shows the $K_s$ spectrum we obtained, with identified spectral features marked. The spectrum shows He I 20581 Å emission, absorption at He I 21126 Å, a weak N II (or C III) emis-
sion feature at 21 155 Å, and moderately strong Bry absorption, typical features of an early supergiant. By comparison with the atlases from [Hanson et al. 1996, 2005a], we can conclude that the star is a B1 Iab type. Together with X-ray properties, this allows us to confirm the nature of the system as an SGXB.

Our preliminary results were published in [Nespoli et al. 2007], and recently confirmed by [Hannikainen et al. 2007], who, from K- and H-band spectra, constrained the spectral type to a B0.5 supergiant. They also estimated the distance of the source as 5 kpc.

### 3.2. Reddening and distance estimation

From the identified spectral types, we obtained the intrinsic colors \((J - K)\) from [Wegner 1994]; we then calculated, from 2MASS photometry, the instrumental colors \((J - K)_{2MASS}\) properly transformed through the formula from [Carpenter 2001] \(^3\) to the [Bessell & Brett 1988] homogenized photometric system in order to estimate the infrared color excess \(E(J - K)\). Assuming the mean extinction law \((R_V = 3.1)\), from \(A_V/E(J - K) = 5.82 \pm 0.10\) [Rieke & Lebofsky 1985], we obtained the total measured visual extinction \(A_V\) and the corresponding hydrogen column density value from \(N_H/A_V = 1.79 \pm 0.03 \times 10^{21} \text{ atoms cm}^{-2}\) mag [Predehl & Schmitt 1995]. We were thus able to compare the retrieved interstellar value of \(N_H\) with the one provided by X-ray data. In our calculation, we estimated errors through error propagation. Errors in the final values of \(N_H\) are mainly due to errors in the infrared colors and of the transformation between the two photometric systems.

We also estimated the distance of the six sources, applying the relation \(M_K = K + 5 - 5 \log d - A_K\). For each source, \(M_K\) was obtained from our proposed spectral type [Wegner 2006], the intrinsic color index \((K - V)\) from [Wegner 1994] was used in order to calculate \(M_K\), and the 2MASS \(K\) magnitude was employed. We derived \(A_K\) from the relation \(A_K/E(J - K) = 2.4(\lambda)^{-1.75}\) for \(\lambda = 2.2 \mu m\) [Draine 1989].

The results of our calculations are given in Table 2, together with some crucial quantities used in the calculations or displayed for comparison. The distance estimation is mainly affected by the uncertainty in the value of the absolute magnitude \(M_K\), which is due to two contributions, the errors given in the tabulated values of \(M_V\) and the uncertainty in the spectral classification, from which the absolute magnitude is determined. The largest role is played by the errors in the mean tabulated values themselves (see Wegner 2006 for more details). The retrieved values for \(d\) must thus be assumed with prudence.

### 4. Discussion

Using near-infrared spectroscopy of six high-energy sources, IGR J16207–5129, IGR J16465–4507, IGR J16479–4514, AX J1841.0–0536, 4U 1907+097 and IGR J19140+0951, we classified our counterparts through comparison with published atlases. We found that all the observed systems have a supergiant companion. Our results, combined with information from X-ray data, is able for the first time to firmly include one source, IGR J16479–4514, in the newly discovered class of the SFXTs. Moreover, we can confirm with infrared data the identification of IGR J16465–4507 and AX J1841.0–0536 as SFXTs, as recently proposed by [Negueruela et al. 2007] from optical spectra.

From our spectral classification, we estimated the distance of the six sources. The retrieved values are consistent with the location of the sources in the Norma (IGR J16207–5129, IGR J16465–4507, AX J1841.0–0536, 4U 1907+097 and IGR J19140+0951) regions respectively. This determination, although affected by some uncertainty, can be considered an a posteriori confirmation of the proposed spectral classification.

This work allowed us to calculate the extinction from IR data for the six systems. Recently, it has been pointed out (see [Kuulkers 2005, Chaty 2007]) that INTEGRAL is revealing two new classes of supergiant HMXBs, the highly obscured HMXBs and the SFXTs. The first ones are characterized by strong intrinsic absorption, the second by strong and short X-ray outbursts. High, variable, hydrogen column densities have in some cases been measured for SFXTs (e.g. IGR J11215–5952: [Smith et al. 2005a], IGR J17391–3021: [Smith et al. 2006b]), suggesting a possible intrinsic absorption for this class as well, and marking a potential overlap between the two new classes. The origin and position (around the compact object only, or enveloping the entire system) of the absorbing material are still a matter of debate, and only multiwavelength studies are able to address the problem, distinguishing between the absorption in X-ray and in the IR/optical bands.

We calculated the effective interstellar extinction \(A_V\) and converted it into hydrogen column density \(N_H\). Our results can be compared with the values obtained from X-ray data. If the two retrieved values are compatible within the corresponding errors, we face two possible scenarios: either the source of absorption

| Object          | Wavelength [Å] | EW [Å] | Wavelength [Å] | EW [Å] | Wavelength [Å] | EW [Å] | Wavelength [Å] | EW [Å] | Wavelength [Å] | EW [Å] |
|-----------------|----------------|-------|----------------|-------|----------------|-------|----------------|-------|----------------|-------|

* Systems classified through this work as new or confirmed SFXTs.
Table 3. For each observed source in the first column, the obtained spectral classification, intrinsic infrared colors, 2MASS photometry, calculated infrared excess, hydrogen column density obtained from X-ray published measurements, effective interstellar column density obtained from our work and distance estimation are reported. See text for corresponding references.

| Source        | Spectral type | $(J-K)_0$ [mag] | $(J-K)_{2MASS}$ [mag] | $E(J-K)$ [mag] | $N_H$ from X-ray data [10$^{22}$ cm$^{-2}$] | Interstellar $N_H$ [10$^{22}$ cm$^{-2}$] | Distance [kpc] |
|---------------|---------------|-----------------|-----------------------|----------------|------------------------------------------|------------------------------------------|--------------|
| IGR J16207-5129 | B1 Ia         | -0.12           | 1.31                  | 1.43           | 3.7$^{+1.4}_{-1.2}$                       | 1.53$^{±0.12}$                           | 6.1 (-3.5, +8.9) |
| IGR J16465-4507 | O9.5 Ia       | -0.15           | 0.69                  | 0.84           | 72$^{±6}_{-6}$                            | 0.87$^{±0.56}$                           | 9.5 (-5.7, +14.1) |

| IGR J19140+0951 | B0.5 Iab      | -0.12           | 1.50                  | 1.62           | $\sim 6^\circ$                           | 1.68$^{±1.5}$                            | 1.1 (-0.8, +2.3) |

* A maximum value of 10.1 ± 0.2 × 10$^{22}$ cm$^{-2}$ was reported by Rodriguez et al. 2005.

5. Conclusions

From near-infrared spectroscopy of the six HMXBs we have found that:

- the proposed optical counterparts were confirmed and the spectral classification of the sources provided;
- one source, IGR J16479-4514, was added to the SFXTs and the confirmation of IGR J16465-4507 and AX J1841.0-0536 as members of the class was proven with infrared data;
- the comparison between $N_H$ obtained from X-ray data and interstellar extinction from our data showed for four systems (IGR J16465-4507, IGR J16479-4514, AX J1841.0-0536 and IGR J19140+0951) the presence of an absorbing envelope, strictly confined around the compact object;
- all the three identified SFXTs are intrinsically absorbed, suggesting that this might be a characteristic of the class;
- the distance estimation, compatible with the location of the sources in the respective galactic arms, is a possible confirmation of the spectral classification provided here.
