Institute of Nuclear Physics, NCSR Αθηνών, 15310 Athens, Greece

Abstract. HELAC–PHEGAS is a FORTRAN based package that is able to compute automatically and efficiently tree-order helicity amplitudes and cross sections for arbitrary scattering processes within the standard electroweak theory and QCD. The algorithm for the amplitude computation, HELAC, exploits the virtues of the Dyson-Schwinger equations. The phase-space generation algorithm, PHEGAS, constructs all possible kinematical mappings dictated by the amplitude under consideration. Combined with multichannel self-optimized Monte Carlo integration it results to efficient cross section evaluation.

INTRODUCTION

The need for efficient algorithms to calculate helicity amplitudes and cross sections for any process, in an automatic way, has been well recognized long time ago. Up to now, algorithms that efficiently combine helicity amplitude computation and phase-space integration have been proven successful for specific processes, like for instance four-fermion (1) production in $e^+e^-$ collisions. On the other hand general-purpose computational packages like CompHEP (2) and GRACE (3) do not provide automatic efficient phase-space integration algorithms. Moreover the vast majority of the automatized helicity amplitude computational algorithms, like for instance MadGraph (4), have been based on the Feynman graph representation of the amplitude which severely restricts their ability to deal with multiparticle scattering processes.

In this article we report on some developments that have lead to the construction of two programs, HELAC (5) and PHEGAS (6), that allow for an efficient and automatic evaluation of cross sections for arbitrary scattering processes.

HELAC

The traditional representation of the scattering amplitude in terms of Feynman graphs results to a computational cost that grows like the number of those graphs, therefore as $n!$ where $n$ is the number of particles involved in the scattering process.

An alternative\(^1\) to the Feynman graph representation is provided by the Dyson-Schwinger approach. Dyson-Schwinger equations express recursively the $n$-point Green’s functions in terms of the $1-, 2-, \ldots, (n-1)$-point functions. For instance in QED these equations can be written as follows:

\[ b^\mu(P) = \sum_{i=1}^{n} \delta_{P_i=P} b^\mu(P_i) + \sum_{P=P_1+P_2} (ig)\Pi^\nu_\gamma \psi(P_2)\gamma^\nu\psi(P_1)\epsilon(P_1, P_2) \]

where

\[ b_\mu(P) = \psi(P) = \bar{\psi}(P) = \psi(P) \]

describes a generic $n$-point Green’s function with respectively one outgoing photon, fermion or antifermion leg carrying momentum $P$. $\Pi^\nu_\gamma$ stands for the boson propagator and $\epsilon$ takes into account the sign due to fermion antisymmetrization.

In order to actually solve these recursive equations it is convenient to use a binary representation of the momenta

involved (8). For a process involving \( n \) external particles, all momenta appearing in the computation, \( P^\mu \),

\[
P^\mu = \sum_{i=1}^{n} p_i^\mu,\]

where \( I \subset \{1, \ldots, n\} \), can be assigned a binary vector \( m = (m_1, \ldots, m_n) \), where its components take the values 0 or 1, in such a way that

\[
P^\mu = \sum_{i=1}^{n} m_i p_i^\mu.
\]

Moreover this binary vector can be uniquely represented by the integer

\[
m = \sum_{i=1}^{n} 2^{i-1} m_i,
\]

and therefore all subamplitudes can be labeled accordingly, i.e.

\[
b_\mu(P) \to b_\mu(m), \quad 1 \leq m \leq 2^{n-1}.
\]

A very convenient ordering of integers in binary representation relies on the notion of level \( l \), defined simply as

\[
l = \sum_{i=1}^{n} m_i.
\]

As it is easily seen all external momenta are of level 1, whereas the total amplitude corresponds to the unique level \( n \) integer \( 2^{n-1} \). This ordering dictates the natural path of the computation; starting with level-1 subamplitudes, we compute the level-2 ones using the Dyson-Schwinger equations and so on up to the level \( n \) one which is the full amplitude. For the spinor wave functions as well as for the Dirac matrices, we have chosen the 4-dimensional chiral representation which results to particularly simple expressions. All electroweak vertices in both the Feynman and the Unitary gauge have been included.

The computational cost of HELAC grows like \( \sim 3^n \), which essentially counts the steps used to solve the recursive equations. Obviously for large \( n \) there is a tremendous saving of computational time, compared to the \( n! \) growth of the Feynman graph approach.

For QCD amplitudes colour representation and summation plays an important role. Let \( 1 \ldots n \) denote the colour labels of quarks and \( \sigma(1) \ldots \sigma(n) \) denote the colour labels of antiquarks, with \( \sigma(i), i = 1 \ldots n! \) being a permutation of \( \{1 \ldots n\} \). The colour factor is given obviously by

\[
C_i = \delta_{\sigma(1)} \delta_{\sigma(2)} \ldots \delta_{\sigma(n)}
\]

Moreover the colour matrix, defined as

\[
\mathcal{M}_{ij} = \sum_{\text{colours}} C_i C_j^\dagger
\]

with the summation running over all colours, \( 1 \ldots N_c \), has a very simple representation

\[
\mathcal{M}_{ij} = N_c^m(\sigma_i, \sigma_j)
\]

where \( m(\sigma_i, \sigma_j) - 1 \) counts how many elements of the permutations \( \sigma_i \) and \( \sigma_j \) are common. In order to extent this colour representation to QCD amplitudes we have just to consider gluons as being quark-antiquark pairs and assign to them two colour labels \( (i, \sigma_i) \). The colour factor and the colour matrix still has exactly the same form. The only thing one has to consider is to rewrite the known Feynman rules of QCD in a slight different way. It is worthwhile to note that exact colour summation is efficient as far as the number of equivalent gluons is smaller than \( O(5 - 6) \). For multicolour processes other approaches have to be considered (9, 10).

The programme is also incorporating the possibility to use an extended precision by exploiting the virtues of FORTRAN90. The user can easily switch to a quadruple precision or to an even higher, user-defined precision by using the multi-precision library (11) included in HELAC. In this way, a straightforward computation of cross sections for processes like \( e^- e^+ \to e^- e^+ e^- e^+ \) without any cut is reliably performed (12).

**PHEGAS**

The study of multi-particle processes, like for instance four-fermion production in \( e^+ e^- \), requires efficient phase-space Monte Carlo generators. The reason is that the squared amplitude, being a complicated function of the kinemtical variables, exhibits strong variations in specific regions and/or directions of the phase space, lowering in a substantial way the speed and the efficiency of the Monte Carlo integration. A well known way out of this problem relies on algorithms characterized by two main ingredients:

1. The construction of appropriate mappings of the phase space parametrization in such a way that the main variation of the integrand can be described by a set of almost uncorrelated variables, and
2. A self-adaptation procedure that reshapes the generated phase-space density in order to be as much as possible close to the integrand.

In order to construct appropriate mappings we note that the integrand, i.e. the squared amplitude, has a well-defined representation in terms of Feynman diagrams. It is therefore natural to associate to each Feynman diagram a phase-space mapping that parametrizes the leading variation coming from it. To be more specific the contribution of tree-order Feynman diagrams to the full amplitude...
can be factorized in terms of propagators, vertex factors and external wave functions. In general, the main source of variation comes from the propagator factors and therefore our aim is to construct a mapping that expresses the phase-space density in terms of the kinematical invariants that appear in these propagator factors. Since in principle we need as many mappings as Feynman diagrams for the process under consideration, we have to appropriately combine them in order to produce the global phase-space density. A simple and well studied solution to this problem was suggested some time ago in reference (13).

In order to describe the construction of the phase-space mappings we face the original n! computational cost growth problem, the self-optimization cures to a certain extent this by selecting only the few mappings that dominate the phase-space density. For alternative approaches we refer to (15).

In order to describe the construction of the phase-space mappings, let us consider a typical process in which two incoming particles produce n outgoing ones. The phase space, $d\Phi_n(P=q_1+q_2+p_1,\ldots,p_n)$, can be decomposed as follows

$$d\Phi_n = \frac{1}{2\pi} \prod_{i=1}^{m} \frac{dQ_i}{2\pi} d\Phi_m(P;Q_1,\ldots,Q_m).$$

$$d\Phi_n(Q_1,r_1,r_2,\ldots,r_{n_1}) \cdots d\Phi_n(Q_m,s_1,s_2,\ldots,s_{n_m})$$

where the subsets $\{r_1,r_2,\ldots,r_{n_1}\}$ up to $\{s_1,s_2,\ldots,s_{n_m}\}$ represent an arbitrary partition of $\{p_1,p_2,\ldots,p_n\}$. The above equation can be generalized recursively resulting in an arbitrary decomposition of $d\Phi_n$. Feynman graphs can be seen as a realization of such a decomposition, this latter being identified with a sequence of vertices of the graph. There two possible cases for $2 \rightarrow n$ scattering.

First, all outgoing momenta involved in the vertex are time-like,

$$d\Phi_n = \frac{dQ_1^2}{2\pi} \frac{dQ_2^2}{2\pi} d\Phi_2(Q \rightarrow Q_1,Q_2) \cdots$$

$$= \frac{dQ_1^2}{2\pi} \frac{dQ_2^2}{2\pi} d\cos\theta d\Phi \frac{\lambda^{1/2}(Q_1^2,Q_2^2)}{32\pi^2 Q^2} \cdots$$

with $\lambda(x,y,z) = x^2 + y^2 + z^2 - 2xy - 2xz - 2yz$, and second when one of them is space-like,

$$d\Phi_n = \frac{dQ_1^2}{2\pi} \frac{dQ_2^2}{2\pi} d\Phi_2(Q \rightarrow Q_1,Q_2) \cdots$$

$$= \frac{dQ_1^2}{2\pi} \frac{dQ_2^2}{2\pi} dt d\phi \frac{1}{32\pi^2 Q |q_2|^2} \cdots$$

with

$$t = (Q_1 - q_2)^2$$

$$= m_1^2 + Q_1^2 - \frac{E_2}{Q} (Q^2 + Q_1^2 - Q_2^2) + \frac{\lambda^{1/2}}{Q} |q_2| \cos\theta$$

and $(E_2, q_2)$ being the incoming momentum $q_2$ in the rest frame of $Q$. The appropriate sequence of vertices,
\{V_{1}, V_{2}, \ldots, V_{k}\} can be chosen in such a way that a recursive construction of the phase space is realized. For instance \(V_1\) should contain at least one incoming particle whose momentum is known. The rest of the sequence is chosen recursively: vertex \(V_j\) is characterized by an incoming momentum \(Q\) which has already been generated in one of the \(\{V_1, \ldots, V_{j-1}\}\).

Following the above described algorithm we end up with an expression for the phase-space density,

\[
d\Phi_n \rightarrow \prod ds_i \mathcal{P}_i(s_i) \prod dt_j \mathcal{P}_j(t_j) \prod d\phi_k \prod d\cos \theta_l
\]

where \(s_i\) and \(t_j\) refer to the kinematical invariants entering the propagator factors of the graph and \(\phi_k\) and \(\cos \theta_l\) represent center-of-mass angles needed to complete the phase-space parametrization. It is now straightforward to generate \(s_i\) and \(t_j\) with probability densities \(\mathcal{P}_i(s_i)\) and \(\mathcal{P}_j(t_j)\) that are automatically chosen accordingly to the nature of the propagating particle.

Results, demonstrating the ability of PHEGAS–HELAC to deal with multiparticle processes, are presented in table 1 (6, 16).

**SUMMARY AND OUTLOOK**

PHEGAS–HELAC offers a framework for high-energy phenomenology. It provides all necessary and sufficient tools for efficient, reliable and automatic computation of helicity amplitudes and cross section. The Standard Model, including QCD, has been fully incorporated. Higher-order corrections are in principle tractable within the framework of Dyson-Schwinger equations and work is in progress in order to include electroweak corrections as described in reference (17). New physics interactions and models, including the Minimal Supersymmetric Standard Model and the trilinear gauge couplings will be considered in the near future.
