Background: Glioma is the most frequent brain malignancy presenting very poor prognosis and high recurrence rate. Focal adhesion complexes play pivotal roles in cell migration and act as hubs of several signaling pathways.

Methods: We used bioinformatic databases (CGGA, TCGA, and GEO) and identified a focal adhesion-related differential gene expression (FADG) signature by uniCox and LASSO regression analysis. We calculated the risk score of every patient using the regression coefficient value and expression of each gene. Survival analysis, receiver operating characteristic curve (ROC), principal component analysis (PCA), and stratified analysis were used to validate the FADG signature. Then, we conducted GSEA to identify the signaling pathways related to the FADG signature. Correlation analysis of risk scores between the immune checkpoint was performed. In addition, the correlation of risk scores and genes related with DNA repair was performed. CIBERSORT and ssGSEA were used to explore the tumor microenvironment (TME). A nomogram that involved our FADG signature was also constructed.

Results: In total, 1,726 (528 patients diagnosed with WHO II, 591 WHO III, and 603 WHO IV) cases and 23 normal samples were included in our study. We identified 29 prognosis-related genes in the LASSO analysis and constructed an eight FADG signature. The results from the survival analysis, stratified analysis, ROC curve, and univariate and multivariate regression analysis revealed that the prognosis of the high-risk group was significantly worse than the low-risk group. Correlation analysis between risk scores and genes related with DNA repair showed that the risk score was positively related with BRCA1, BRCA2, RAD51, TGFβ1, and TP53. Besides, we found that the signature could predict the prognosis of patients who received radiation therapy. SsGSEA indicated that the high-risk score was positively correlated with the ESTIMATE, immune, and stromal scores but negatively correlated with tumor purity. Notably, patients in the high-risk group...
INTRODUCTION

Glioma account for the largest proportion of malignant craniocerebral tumors (1). The currently available treatments include total resection, radiotherapy, and chemotherapy. The National Comprehensive Cancer Network (NCCN) guideline recommends chemoradiation +/- tumor treatment fields (TTFs) for adjuvant treatment in primary diagnosed GBMs. Clinical cancer studies have advanced in recent years, although the overall survival (OS) has not improved (2). Patients with high-grade glioma who receive concurrent temozolomide and postoperative radiation achieve a median survival of only 14.6 months. Meanwhile, patients receiving radiotherapy alone achieve a median survival of only 12.1 months. Glioma are highly aggressive and have high fatality rates (3).

Glioma has been classified into four grades by the World Health Organization (WHO) 2016 Classification of glioma. Low-grade glioma (WHO II) includes oligodendrogliomas and astrocytomas, while WHO III includes anaplastic oligodendrogliomas, anaplastic astrocytomas, anaplastic oligoastrocytomas, and anaplastic ependymomas. Glioblastoma (GBM) has been defined as high-grade glioma, which is resistant to chemoradiotherapy (4).

Immunotherapy is an emerging method of treatment for several kinds of cancer, such as breast cancer, lung cancer, and prostate cancer (5, 6). However, there is no efficient treatment for progressive disease in glioma and there is an urgent need for efficient management strategies.

Focal adhesion involves multiprotein complexes that act to anchor the actin cytoskeleton to the extracellular matrix (ECM). These complexes consist of integrins and actins, structural proteins including vinculin, talins, and signaling molecules such as focal adhesion kinase (7). In cancer cells, adhesion to the ECM may mediate radioresistance, chemotherapy, and resistance to targeted therapy (8). Focal adhesions can interact with the stroma signaling pathways and cooperate with downstream targets of integrins and growth factor receptors. These complexes play a pivotal role in cell survival, proliferation, differentiation, and invasion. Integrins are catalytically inactive receptors, which combine with the ECM directly and activate downstream signal transduction (9). Integrins promote a special type of EMT in glioma that endows cancer cells with the ability of metastasis (10). The conformational memory of integrin reinforces the assembly of focal adhesions and induces cell migration (11). Inhibition of the focal adhesion signaling pathway may be a promising therapeutic target for gliomas.

In this study, we mined the online databases including the Gene Expression Omnibus (GEO), The Cancer Genome Atlas (TCGA), and the Chinese Glioma Genome Atlas (CGGA), and constructed a focal adhesion-related differential gene expression (FADG) signature in glioma. We found that the FADG signature was associated with prognosis, radiation response, and the immune microenvironment, and especially with immune cell infiltration. Our results revealed that this FADGs signature could accurately predict the prognosis and provide precise guidelines for the treatment of glioma.

MATERIALS AND METHODS

Dataset Retrieval

Data from a total of 180 samples from glioma patients including 23 normal samples and 157 cases were obtained from the Gene Expression Omnibus database, expression profiling arrays (dataset GSE4290), and platform GPL570 (https://www.ncbi.nlm.nih.gov/). In total, 1,018 mRNA sequences from glioma patient samples and their corresponding clinical information were collected from the CGGA database as the training and internal cohort (http://www.cgga.org.cn/index.jsp). RNA sequence and clinical data including 449 LGG and 143 GBM from the TCGA database as the external validation cohort. Overall, 199 focal adhesion genes were retrieved from the MSigDB database (https://www.gsea-msigdb.org/gsea/msigdb).

Identification of Focal Adhesion-Related Differential Expression Genes

The GSE4290 database was mined to identify the differentially expressed genes (DEGs), which were then analyzed by the R software 4.0.0. setting a gene expression threshold of [log fold change (FC)] > 1 and false discovery rate (FDR) < 0.05. FADGs were filtered, which overlapped with the focal adhesion-relevant genes and DEGs. A Protein-protein interacting (PPI) network of these candidate genes was constructed using STRING (https://www.string-db.org/). These candidate genes underwent univariate regression analysis in R using the CGGA data including RNA sequencing, OS, and living status data.
**Construction of the Focal Adhesion-Relevant Signature**

Patient data from the CGGA were randomly divided into two cohorts: a training cohort and a testing cohort. Next, the least absolute shrinkage and selection operator (LASSO) regression analysis was performed to remove collinearity among these genes. DEGs and survival probability associated of these genes were analyzed using the GEPYA database (http://gepia.cancer-pku.cn/). Immunohistochemistry images were obtained from the Human Protein Atlas (HPA) database (https://www.proteinnatlas.org/). A prognosis-related signature was conducted based on the expression of the candidate genes and regression analysis coefficient values. The algorithm was as follows:

\[ \text{riskscore} = \sum_{i=1}^{n} (\text{Coefi} \times X_i) \]

A patient risk score was calculated using this formula, and was used to stratify patients according to the median risk score into low- and high-risk groups. 'SurvivalROC' R package, Harrell’s concordance index to assess the predictive value of the FADGs signature for prognosis.

**Validation of the Focal Adhesion-Related Differential Genes Signature**

The training cohort and testing cohorts from the CGGA and TCGA validation cohorts were used for the following analysis. Missing clinical data were eliminated. 'Survival' and 'survminer' packages were utilized in R to perform a survival probability between the high- and low-risk groups. The ‘SurvivalROC’ package was utilized to perform receiver operating characteristic (ROC) curve analysis to verify the accuracy of the model for the 1-, 3-, and 5-year survival. Survival risk was plotted by R using the 'riskplot' package. Next, 'scatterplot3d' was used to perform principal component analysis (PCA). Stratification analysis of the TCGA and CGGA datasets was plotted in R for the high- and low-risk groups. Multivariate and univariate Cox regression analysis was plotted for both the training and testing cohorts. Harrell’s concordance index was also programmed.

**GSEA Was Performed to Identify the Involved Gene Pathways**

Hallmark, Gene Ontology (GO), and Kyoto Encyclopedia of Genes and Genomes (KEGG) analysis between the low- and high-risk groups was conducted using GSEA_4.1.0 to explore the functional annotation of the DEGs and for the systematic analysis of the gene functions (h.all.v7.2.symbols, c2.cp.kegg.v7.2.symbols, c5.go.v7.2.symbols). The results were filtered by Normalized Enrichment Score (NES) > 1 and FDR q-val < 0.05.

**Correlation Analysis of Focal Adhesion-Related Differential Gene Signature and Radiation Response**

Correlation analysis between genes that related with DNA repair and risk score were programmed using the training and testing cohorts in the CGGA database. Radiation response of patients after radiation therapy were extracted from the TCGA cohort. Differential analysis of the risk scores of complete remission (CR) and progression disease (PD) were analyzed.

**Correlation Analysis of Focal Adhesion-Related Differential Gene Signature and Immune Cell Infiltration**

Single-sample gene set enrichment analysis (ssGSEA) is an algorithm used to evaluate the level of immune cell infiltration in a single sample according to the expression levels of immune cell-specific markers. Patients in the CGGA training cohort and testing cohort were imported for the ssGSEA analysis. Patients with glioma were analyzed by R using the 'limma', 'GSVA', and 'GSEABase' packages. Next, samples with risk scores were imported into ESTIMATE, for the Estimation of Stromal and Immune cells in malignant tumor tissues using Expression data analysis, to verify the ssGSEA results. We performed a correlation analysis between the risk score and ESTIMATE, stromal, and immune scores, and tumor purity. Next, the correlation between the risk score and expression of immune check point was analyzed. CIBERSORT was performed to analyze the 22 distinct leukocyte subsets in the tumors based on bulk transcriptome data to detect the tumor purity and to explore the TME using the ‘e1071’ and ‘parallel’ packages.

**Establishment of the Nomogram**

A nomogram was constructed using the CGGA cohort to predict the prognosis of patients combining the clinical features and risk scores to assess the accuracy of the model. A calibration curve was generated to evaluate the accuracy of the nomogram. To demonstrate the incremental value of the FADGs signature over the clinicopathological characteristic for an individualized assessment of the OS, the decision curve was constructed.

**Statistical Analysis**

R software version 4.0.0 (Statistics Department of the University of Auckland) with corresponding packages 160 and Graphpad Prism, version 7 (GraphPad Software,San Diego, California USA) were used for statistical analyses. A P-value < 0.05 was considered statistically significant.

**RESULTS**

**Analysis of Differentially Expressed Genes in Glioma Patients Correlated With Focal Adhesion**

A flow chart to illustrate the workflow used in our study is shown in Figure 1. The features of patients enrolled in this study are listed in Table 1. To identify the DEGs, the GSE4290 dataset from the GEO database was extracted. There was a total of 2,450 DEGs between glioma patients and normal brain tissues. Genes covering 1,450 upregulated and 1,425 downregulated were plotted in a volcano plot (Figure 2A). A total of 37 FADGs were selected from the overfitting group of 2,450 genes and 199 focal adhesion relevant genes (Figure 2B). Then, univariate regression analysis was performed and 29 genes associated with the prognosis were

NA, Non available.
selected as candidate genes filtering with a threshold of \( P < 0.05 \) (Figure 2C). A heatmap of gene expression for each patient was plotted (Figure 2D). A PPI network was constructed involving the 37 FADGs (Figure 2E); the network comprised 29 genes and 144 interacting mechanisms.

**Candidate Genes for the Focal Adhesion-Related Risk Signature**

To identify the association with clinical information, we used 970 samples with available OS data and living status information from the CGGA database for the subsequent analysis. We divided 486 patient samples into the training cohort and 484 samples into the testing cohort. The candidate genes were analyzed using the LASSO regression analysis to exclude overlapping genes (Figures 2F, G), and multivariate Cox proportional risk regression analysis was performed (Figure 2H). Eight genes were obtained from the analysis: COL1A2, COL4A1, ITGB4, MAPK10, PRKCB, PRKCG, RELN, and TNC. COL1A2, MAPK10, and PRKCB genes were identified as low-risk genes, while COL4A1, ITGB4, PRKCG, RELN, and TNC were defined as high-risk for the OS in patients with glioma. The differential expression of each gene and immunochemistry images were obtained from online databases (Supplementary Figures 1 and 2).

A focal adhesion relevant prognostic signature was constructed using the following formula:

\[
\text{Risk score} = (-0.16036 \times \text{COL1A2 expression}) + (0.321935 \times \text{COL4A1 expression}) + (0.115143 \times \text{ITGB4 expression}) + (-0.18388 \times \text{MAPK10 expression}) + (-0.20014 \times \text{PRKCB expression}) + (0.181394 \times \text{PRKCG expression}) + (0.182231 \times \text{RELN expression}) + (0.251663 \times \text{TNC expression})
\]

Patients were divided into high- and low-risk groups according to the median of the risk score.

**Clinical Features of the Focal Adhesion-Related Differential Genes Signature in the Low- and High-Risk Groups**

To clarify the relationship between the prognosis and FADGs signature, we analyzed the clinical information of 486 samples in the training cohort, 484 samples in the testing cohort for internal validation.
authentication, and 603 samples in the TCGA database for external validation. The results of the analysis of the training cohort are shown in Figure 3. Low- and high-risk groups were stratified according to the median of the risk score (Figure 3A). Expression levels of the eight genes from the training cohort are shown in Figure 3B. Survival time of high-risk patients tended to be worse than low-risk patients (Figure 3C). The survival probability of the high-risk score group was significantly lower than that of the low-risk group [hazard ratio (HR) = 0.02, 95% confidence interval (CI) = 0.15–0.25, P < 0.001, C-index = 0.685] (Figure 3D). Patients could be stratified into two groups according to our risk score (Figure 3E). The areas under the curve for the 1-, 3-, and 5-year survival were 0.721, 0.786, and 0.765, respectively (Figure 3F).

Univariate regression analysis showed that this signature could predict the prognosis of patients with glioma and resulted to be an independent prognostic factor from the multivariate regression analysis (Supplementary Figures 3A, B). In summary, our signature was a sensitive prognostic model for the risk stratification of patients with glioma.

To increase the credibility of our model, we performed the same analysis using the CGGA internal authentication cohort and TCGA external validation cohort. Survival time of patients with high-risk scores tended to be shorter than patients with low-risk scores (Figures 4A, B). The survival probability of the high-risk group was significantly lower in both cohorts (CGGA: HR = 0.29, 95% CI = 0.23–0.36, P < 0.001, C-index = 0.661); (TCGA: HR = 0.28, 95% CI = 0.20–0.39, P < 0.001, C-index = 0.660) (Figures 4C, D). Patients from the CGGA testing and TCGA databases could be stratified into two subgroups distinctly by PCA analysis (Figures 4E, F). ROC curves were plotted and the areas under the curve for the 1-, 3-, and 5-year survival in the CGGA testing cohort were 0.728, 0.767, and 0.788, respectively, (Figure 4G) and 0.779, 0.851, and 0.787, respectively, in the TCGA validation cohort (Figure 4H). Univariate regression analysis and multivariate regression analysis demonstrated the 8-gene signature was an acute prognostic factor (Supplementary Figures 3C, D). The same with the CGGA training cohort, our signature was a sensitive prognostic model.

Next, a stratified analysis was performed using both the CGGA and TCGA databases (Figure 5 and Supplementary Figure 4). Patients in the CGGA were stratified by grade, gender, age, IDH mutational status, 1p19q co-deletion status, MGMT methylation status, and PRS status. And in the TCGA
cohort were stratified by grade, sex, age, IDH mutational status, and 1p19q co-deletion status. According to the FADGs signature, the survival probability of patients in the high-risk group was significantly lower than that in the low-risk group (P < 0.001), except for the WHO II subgroup (P = 0.052). These findings indicated that the FADG signature played a certain role in predicting the prognosis of glioma patients.

**Gene Set Enrichment Analysis**

Gene set Enrichment analysis was programmed between the high- and low-risk groups with a threshold of NES > 1 and FDR q-val < 0.05. In the Hallmark analysis, the APOPTOSIS and G2M CHECKPOINT pathway was enriched (Figure 6A). In the KEGG analysis, the KEGG_EC_M_INVIRONMENT_INTERACTION pathway was enriched (Figure 6B), while GO analysis revealed that the GO_EXTRACELLULAR_STRUCTURE_ORGANIZATION, GO_COLLAGEN_METABOLIC_PROCESS, GO_COLLAGEN_BINDING, and GO_EXTRACELLULAR_MATRIX_STRUCTURAL_CONSTITUENT components were enriched (Figure 6C).

**Relationship Between Radiation Response and the Focal Adhesion-Related Differential Gene Signature**

To discover the relationship between the radiation response and our FADG signature, we performed a correlation analysis between genes that related to DNA repair and our FADG signature. Our signature is positively correlated with BRCA1 (r = 0.590, P < 0.001) (Figure 7A), BRCA2 (r = 0.480, P < 0.001) (Figure 7B), RAD51 (r = 0.500, P < 0.001) (Figure 7C), TGFBI (r = 0.470, P < 0.001) (Figure 7D), and TP53 (r = 0.350, P < 0.001) (Figure 7E). The risk scores of patients in the CR group were significantly lower than in the PD group (P = 0.028) (Figure 7F).

**Relationship Between the Tumor Immune Microenvironment and the Focal Adhesion-Related Differential Gene Signature**

To identify the potential relationship between immune cell infiltration and our FADG signature, we performed ESTIMATE analysis and CIBERSORT analysis. From the ESTIMATE analysis,
patients with high-risk scores tended to gather in the IMMUNITY_H group. High-risk score group was positively correlated with the ESTIMATE, immune, and stromal scores and conversely, negatively correlated with tumor purity (Figure 8A). To verify whether there was a statistically significant association, correlation analysis was performed (Figures 8B–E). CIBERSORT was performed to explore the status of immune cell infiltration. Bar plots showed the proportion of immunocytes in each patient (Supplementary Figure 5A). Furthermore, levels of resting memory CD4+T cells (P = 0.003), follicular helper T cells (P < 0.001), regulatory T cells (Tregs)(P = 0.01), gamma delta T cells (P = 0.009), and M0 macrophages (P < 0.001) were significantly positively related with the risk score, while levels of naïve CD4+T cells (P < 0.001), activated NK cells (P = 0.014), and monocytes (P < 0.001) were significantly negatively related with the risk score (Supplementary Figure 5B). The correlation heatmap showed the correlation between the risk score and immunocyte levels (Supplementary Figure 5C). Finally, a correlation analysis between our signature and immune check points was conducted. Our signature positively correlated with levels of B7-H3 (r = 0.660,
P < 0.001, CTLA4 (r = 0.230, P < 0.001), LAG3 (r = 0.220, P < 0.001), PD-L1 (r = 0.460, P < 0.001), and TIM3 (r = 0.450, P < 0.001), and negatively correlated with PD-1 (r = -0.330, P < 0.001) (Figures 9A–F). These results showed that our model was closely correlated with immunocyte infiltration and immune check points.

**Construction and Evaluation of the Nomogram**

To create a sensitive predictive model of prognosis, a nomogram was constructed using data from the CGGA cohort. Each clinical feature and the relative risk score were considered to calculate the total point score. A probability of the 1-, 2-, and 3-year OS was
reflected by the total points shown in Figure 10A. To estimate the validity of the nomogram, calibration plots were programmed. The calibration plots revealed that the nomogram had a good stability for predicting the actual 3-year OS (Figure 10B). Decision curve analysis (DCA) was used to calculate the incremental value in adding the FADG score to the nomogram. Obviously, the prediction level of adding the FADG score to the nomogram was significantly higher than that of the normal (Figure 10C). Based on the above analysis, our focal adhesion-relevant signature score could predict the OS of patients with glioma.

**DISCUSSION**

Glioma represents 81% of all malignant craniocerebral tumors (12). Glioma, and especially GBM, is characterized by highly malignant disease, death, and recurrence rates, and accounts for 50% of these malignancies (13). Some molecular features have been adopted in the clinical practice, for example, IDH mutational status and MGMT methylation are considered markers of a better prognosis. Although advances in immunotherapy have improved outcomes for some cancers, there is still a significant challenge for the optimal management of glioma (14).

Focal adhesion is at the center of signaling pathways crucial for tumor development (15). Focal adhesion molecules act as binding sites within the cell and matrix to allow integrin binding and induction of cell migration (16, 17). Cells extend protrusions to migrate and transmembrane receptors, which are the stabilizer of these cellular protrusions, anchor to the actin cytoskeleton via FA complexes to provide cells the power to undergo migration (18). Leukocytes migrate to the peripheral tissue to perform immune surveillance functions (18). In the TME of glioma, glioma-associated microglia or macrophages and myeloid-derived suppressor cells represent the most infiltrated cell types, and their levels have been shown to be negatively correlated with the prognosis. Furthermore, myeloid-derived suppressor cells can inhibit the cytotoxic responses mediated by NK cells (19).

We identified a FADG signature by mining databases, which included COL1A2, COL4A1, ITGB4, MAPK10, PRKCB, PRKCG, RELN, and TNC. Some studies found that COL1A2 was a crucial gene regulating cell migration by the cytoskeleton. Silencing of COL1A2 inhibited gastric cancer progression (20). Wang et al. demonstrated that COL4A1 promoted metastasis in hepatocellular carcinoma (21). ITGB4 maybe an early detector and a prognostic element for colorectal cancer (22). MAPK10, also known as JNK3, suppressed the expression of JNK3 and enhanced the toxicity of paclitaxel in head and neck cancer cells.

(F) Correlation analysis of risk score and gene TIM3 levels.
The activation of PRKCB accelerated the mitochondrial accumulation and the redox response to enhance signaling transduction pathways in cancer cells (24). Polymorphism of SNP rs454006 in PRKCG was demonstrated to increase the risk of patients with osteosarcoma (25). RELN regulated the migration of glioma cells, and activation of the RELN-related pathway could suppress the proliferation of GBM cells (26). TNC was found to support the aggressiveness of breast cancer cells and promote micrometastases (27). In our study, patient samples were scored using our FADGs signature, and was able to stratify patients into high- and low-risk groups according to the median risk score. We used the CGGA training cohort to conduct a survival analysis, ROC curves, PCA, stratification analysis, and multivariate and univariate regression analysis. Our findings demonstrated that the identified gene signature was a valuable parameter for predicting the prognosis. We achieved similar results using an internal authentication cohort and external validation cohort.

We performed gene set enrichment analysis to explore the mechanisms about the FADG signature. Our signature was enriched in apoptosis and G2M check point which is related with the cell cycle from the results. Cell cycle is the decisive factor of radiation sensitivity. Cells in the G2-M phase is most sensitive to ionizing radiation (28). Then, we found that our signature was closely related with genes that related with DNA repair. Patients after radiation with BRCA1 mutation had a better prognosis was identified by Kan (29). BRCA2-mediated cell survival suffered from radiation (30). Inhibition of RAD51 enhanced the radiation sensitivity of glioma stem cells (31). Radiation could activate the TGF-beta1 signaling pathway and induce radiation resistance (32). P53 enhanced the process of DNA repair and lead to the failure of radiation therapy (33). The risk score of patients in the complete remission group was significantly lower than those with progression disease. In short, we considered that the FADG signature could predict the response of radiation therapy.

Immune cells exercised their immune surveillance function by cell migration. The tumor immune microenvironment is complicated in glioma. Glioma-related myeloid cells exert a significant effect to promote the aggressiveness of glioma cells (11). To explore the brain immune microenvironment of patients with glioma, we conducted ssGSEA and CIBERSORT. Correlation heatmap showed that the ESTIMATE score, immune score, and stromal score increased as the risk score increased, and conversely, tumor purity decreased. We performed a correlation analysis to validate the results. The risk score is positively correlated with the ESTIMATE, immune, and stromal scores, and negatively correlated with tumor purity. These results indicated that in the tumor immune microenvironment, the infiltration of immune cells was higher in high-risk glioma patients. Our findings were consistent with previous studies indicating that the degree of tumor infiltration of immune cells increased with an increasing grade (34). Our results from the CIBERSORT analysis confirmed the notion that glioma cells were enriched by the secretion of immune cells, such as leukocytes, CD4+T cells, and Tregs (35). In the tumor immune microenvironment of glioma, polarization of M2...
macrophage has been reported to lead to the malignant biological behavior of glioma cells (36). High infiltration of regulatory T cells was strongly associated with a poor prognosis (36). In this study, we determined that there were more M2 macrophages and regulatory T cells in the high-risk group than other cell types. The ECM played an important role in cell migration and immune response (37). Furthermore, we found that several pathways relevant to the ECM were enriched. Immune checkpoints inhibitors have shown a surprising efficacy in many malignancies, such as lung cancers, gastric cancers, breast cancers, and glioma (2, 6, 38, 39). B7-H3 is a molecule in the B7 family which has been reported to be overexpressed in non-small cell lung cancer, and positively correlated with lymph node metastasis and TNM stage. In addition, B7-H3 has been associated with Tregs levels (40). Cytotoxic T Lymphocyte antigen 4 (CTLA-4) has been shown to inhibit the function of T cell activation, suppressing the immune system function (41). Sustained co-expression of lymphocyte activation gene-3 (LAG3) on T cells also impaired the function of T cells leading to dysfunction of the cellular immunity (42). Programmed cell death protein-1 (PD-1) binds with programmed cell death-1 ligand 1 (PD-L1) and inhibits the activation of T cells, resulting in dysfunction of the immune surveillance (43). High expression of T cell immunoglobulin and mucin domain-containing protein 3 (TIM3) has been positively correlated with a shorter OS, and its co-expression with PD-1 is associated with a poor prognosis (34). Our risk score was positively correlated with B7-H3, CTLA-4, LAG3, PD-L1, and TIM3 expression, while it was negatively correlated with PD-1 expression. We propose that our signature may represent a new approach to guide clinical treatment by immunotherapy.

Nonetheless, our study presented some limitations. First, the clinical features obtained from the TCGA database were incomplete and lacked the MGMT methylation status and PRS types. Second, our study requires experimental validation both in vivo and in vitro. Third, the CGGA database only consisted of Chinese patient samples.

**CONCLUSION**

Our focal adhesion relevant signature combined with the clinical features may predict patient prognosis more accurately and may represent a new approach to the management of immunotherapy treatment for patients with glioma.

**DATA AVAILABILITY STATEMENT**

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found in the article/Supplementary Material.

**ETHICS STATEMENT**

Ethical review and approval were not required for the study on human participants in accordance with the local legislation and institutional requirements. Written informed consent for participation was not required for this study in accordance with the national legislation and the institutional requirements.

**AUTHOR CONTRIBUTIONS**

XX was responsible for the overall design of this study. GW, HL, and WW analyzed the data and edited the manuscript. JP contributed the study guidance of R software. HZ examined the data analysis. XH and LS provided R language modification. HZ revised the discussion of the article. LH contributed the study design. All authors contributed to the article and approved the submitted versions.

**FUNDING**

This study was supported by the Key R&D program of Hebei Province (19277737D).
