Calcitonin secreting neuroendocrine neoplasms of the lung: A systematic review and narrative synthesis.

Abstract

Calcitonin-secreting neuroendocrine neoplasms of the lung are rare, with few cases reported in the literature. Differentiating between medullary thyroid carcinoma and an ectopic source of calcitonin secretion can represent a complex diagnostic conundrum for managing physicians, with cases of unnecessary thyroidectomy reported in the literature. This manuscript reports a case of ectopic hypercalcitonaemia from a metastatic neuroendocrine neoplasm of the lung with concurrent thyroid pathology and summarises the results of a systematic review of the literature.

Medical Literature Analysis and Retrieval System Online, Excerpta Medica, Cochrane Central Register of Controlled Trials, ClinicalTrials.gov and SCOPUS databases were systematically and critically appraised for all peer reviewed manuscripts that suitably fulfilled the inclusion criteria established a priori. The protocol for this systematic review was developed according to the Preferred Reporting Items for Systematic review and Meta-Analysis Protocols, and followed methods outlined in The Cochrane Handbook for Systematic Reviews of Interventions. This systematic review is registered with PROSPERO.

It is vital to consider diagnoses other than medullary thyroid carcinoma when presented with a patient with raised calcitonin, as it is not pathognomonic of medullary thyroid carcinoma. Lung neuroendocrine neoplasms can appear similar to medullary thyroid carcinoma histologically, they can secrete calcitonin and metastasize to the thyroid. Patients with medullary thyroid carcinoma may show stimulated calcitonin values over two or more times above the basal values, whereas calcitonin-secreting neuroendocrine neoplasms may or may not show response to stimulation tests. The present review...
summarises existing evidence from cases of ectopic hypercalcitonaemia to lung neuroendocrine neoplasms.

1. Introduction

Neuroendocrine neoplasms (NENs) are a group of tumours that can often synthesise and secrete biologically active substances. This can lead to an array of clinical presentations, also referred to as paraneoplastic syndromes (PNS) (1).

PNS can occur as either the neoplasms acquire the ability to secrete a variety of biologically active substances, or by cross-reactivity between neoplastic and normal tissue (1,2,3,4). The secretions from neoplasms can be eutopic, meaning from an expected site of origin which would usually secrete such a substance, or ectopic, referring to cells that would not normally be associated with secretion of that substance. The ectopic secretion of biological substances such as peptides, amines or cytokines are more commonly seen by neoplasms that are formed in the gut (2,4,5). Endocrine PNS is the term used when PNS is from ectopic secretion of a hormone, and can lead to diagnostic uncertainty, as it can manifest with symptoms identical to a neoplasm in the expected site of origin. (4,6,7).

Calcitonin (CTN) is secreted from parafollicular cells located in the thyroid gland, but also can be present in the lung, bladder, small intestine, liver, thymus and parathyroid glands. Parafollicular cells are part of the neuroendocrine system and originate from primordial C cells (8,9). The gene Calc-1 creates procalcitonin, which is cleaved by a convertase enzyme to create CTN (5). In in vitro experimental models, CTN has a temporary effect on impairing osteoclast function by reducing its motility, inhibiting carbonic anhydrase II and preventing the development of mature osteoclasts. This, along with its effects on tubular epithelium within the kidney, reduces serum calcium and phosphate levels (8). However, the significance and biological role of CTN remains elusive.
High serum CTN concentrations may be suggestive of MTC but are not pathognomonic (9). MTC is a NEN originating from the thyroid and associated with eutopic secretion of CTN. However, CTN can also be raised due to chronic renal failure, pernicious anaemia, hepatic cirrhosis, various medications, extra-thyroid neoplasms, false positive CTN assay laboratory results, lower respiratory tract infections, smoking, chronic inflammatory conditions of the lung, and any condition increasing gastrin or calcium such as hyperparathyroidism or Zollinger-Ellison Syndrome (7,8,10,11). These conditions tend to cause a moderate rise in CTN compared to MTC. Extra-thyroidal NENs, however, lead to a diagnostic dilemma as they can be associated with similar concentrations of CTN to MTC. Extra-thyroidal sources associated with abnormal CTN concentration have been observed in NENs within the pancreas, parathyroid glands, larynx, oesophagus, thymus, lung, small intestine, liver, bladder and adrenals, all of which can resemble MTC histologically (3,5,10,12).

Around 1% of normal pulmonary tissue is made up of neuroendocrine cells, which can be solitary cells throughout the lung or form in clusters called neuroepithelial bodies (13,14,15). They remain in adult lungs, and continue to secrete bioactive substances such as calcitonin, calcitonin gene-related peptide, serotonin, chromogranin A, and gastrin-related peptide (15,16,17). Physiological stimuli, such as hypoxia, can lead to such agents being secreted (16), which may be why Machens et al. report fluctuations of hypercalcitonaemia in patients with chronic lung disease (10). There is speculation that neuroendocrine cells are the origin of lung NENs, but as we do not yet have evidence of the events of early cell change into neoplasm, this cannot be claimed definitively (16). However, around 25% of lung carcinomas (mainly small and large cell lung carcinomas) can develop neuroendocrine features and may be associated with endocrine PNS (7,14). The development of an endocrine PNS may be what initially leads to the diagnosis of a carcinoma, or its recurrence in cases of patients with known malignancy (4,18).
Extra-thyroidal CTN-secreting NENs can be indistinguishable from MTC in terms of immunohistochemical and biochemical profiles (4,6). Due to the above similarities, biopsies with immunohistochemical characteristics of MTC, along with serum hypercalcitonaemia, could lead to an incorrect diagnosis of MTC. There have been cases of inappropriate thyroidectomy performed in patients with hypercalcitonaemia of extra-thyroidal origin due to concern of MTC (6,8). We now report the diagnostic work-up of a patient found to have a lung lesion and a biopsied gluteal mass with histological appearances of MTC, in the context of morphological thyroid gland abnormalities and concurrent hypercalcitonaemia, and review the relevant literature.

2. Methodology

This protocol was developed according to the Preferred Reporting Items for Systematic review and Meta-Analysis Protocols (PRISMA-P), and followed methods outlined in The Cochrane Handbook for Systematic Reviews of Interventions15. This systematic review has been registered with PROSPERO (International Prospective Register of Systematic Reviews) with registration number CRD42021228917.

2.1 Search Strategy

Two reviewers (DL and GKD) conducted systematic searches of the following databases: Medical Literature Analysis and Retrieval System Online (MEDLINE), Excerpta Medica (EMBASE), Cochrane Central Register of Controlled Trials (CENTRAL), ClinicalTrials.gov, SCOPUS databases. Our key MeSH (Medical Subject Heading) search terms were; “paraneoplastic” OR “ectopic” OR “neuroendocrine” AND “calciton...” AND “lung”.

Moreover, reference lists of selected articles and other literature sources were browsed to ensure a comprehensive literature search was completed. None of the database searches
filtered results based on year of publication date, and the last search was carried out in January 2021.

2.2 Study Selection

Expert opinion manuscripts, letters to the editor, commentaries, conference papers, animal studies, meta-analyses, and articles not in English, were excluded. Data were only included on adults (18 years or older), men and non-pregnant women. Articles were included if they examined from a lung lesion. No restrictions were made regarding the intervention type where a study took place, the number of participants or the duration of follow up. Covidence systematic review software ((Veritas Health Innovation, Melbourne, Australia; http://www.covidence.org) was used for manuscript screening and extraction. Publications were initially screened for any duplicates before being assessed independently and in parallel by two reviewers. Any conflicts regarding the inclusion of a study were met with discussion and consensus. If an agreement had not been reached, arbitration by a third reviewer was utilised.

2.3 Data extraction

Data were extracted independently by two reviewers following the Cochrane Public Health Group Data Extraction and Assessment Template to construct our own data extraction template that was pilot-tested and systematically used for each article. Data extracted included; study description (e.g. title, primary author, publication year, type of study, number of participants, type of lung CTN producing neoplasm and follow-up duration). The primary outcome was the incidence of calcitonin-secreting lung NENs.
2.4 Quality Assessment

Each study was assessed for bias using the Newcastle-Ottawa scale for observational studies. Studies were evaluated on eight factors, categorised into three groups: selection (including whether the cohort is representative of the population), comparability (assessed on grounds of study design and the analysis performed) and outcome (i.e., the assessment of outcome, follow-up rate and adequacy follow-up period).

Stars were awarded per category, with a maximum of four, two and three stars possible for the ‘selection’, ‘comparability’ and ‘outcome’ categories respectively. By following the guidelines of the Newcastle-Ottawa scale\textsuperscript{16}, two reviewers assessed the studies to be of poor (3 stars or less), fair (4-6 stars) or good (7-9 stars) quality.

2.5 Data Synthesis and Statistical Analysis

Heterogeneity was visually inspected, and due to the high variability and insufficient data results were not pooled into a meta-analysis, and a narrative synthesis was conducted instead.

3. Results

Our advanced search produced 327 manuscripts that were imported for screening against predefined criteria. There were no duplicate studies and all 327 manuscripts were screened against title and abstract which resulted in 29 manuscripts progressing to a full-text assessment. A further 6 manuscripts were excluded as they were not in English, resulting in 23 eligible manuscripts.

The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA-P) flow diagram is shown in figure 1, outlining the outcomes of the screening proce
4. Case report

A 72 year-old Caucasian female presented in January 2020 with weight loss and a gluteal mass. She had no major co-morbidities and was not on any regular medications. She had noted gradual weight loss which had started since August 2019, with recurrent ear infections. She suffered with intermittent loose stools but no flushing, later diagnosed as terminal ileitis.

She subsequently had a chest, abdomen and pelvis (CAP) contrast-enhanced computed tomography (CT) which showed bilateral pulmonary emboli, and a large 4 x 4.5cm mass within the right upper lobe of the lung (figure 2). Furthermore, there was evidence of a large retrosternal thyroid goitre and no further evidence of any intra-abdominal abnormalities. An enhancing lesion in the left gluteus was seen, thought to be in keeping with a soft tissue metastasis.

She was referred for a \(^{18}\) fluoro-deoxyglucose positron emission tomography (\(^{18}\)FDG-PET) which showed normal metabolic activity throughout the thyroid, including the retrosternal goitre. There was intense uptake (SUV max \(>4.5\)) within the 4.5cm right upper lobe lung and gluteal mass (figure 3).

A biopsy of the left gluteal lesion showed fibro-fatty tissue infiltrated with malignant cells arranged predominantly with solid sheets. The cells had abundant eosinophilic cytoplasm and eccentric nuclei with frequent nuclear inclusions noted (Figure 4A). Malignant cells were positive for cytokeratin AE1/3, TTF1, PAX-8, synaptophysin and calcitonin, with granular staining for CEA (Figure 4B). Staining for chromogranin A, S100, Melan A, CD45, Napsin A, thyroglobulin and p40 was negative (Figure 4C). The Ki-67 proliferation index was high at 84%. The morphology and immunophenotype was most in keeping with metastatic medullary thyroid carcinoma, although other metastatic neuroendocrine neoplasms could not be completely excluded.
She was also referred for a neck ultrasound scan (USS) which showed a 2.6cm left confluence of spongiform thyroid nodules, with hypoechoic halos (U2). There was no cervical lymphadenopathy (figure 5).

Following discussion in the thyroid cancer multi-disciplinary team meeting, her left thyroid confluence was upgraded to U4 using British Thyroid Association (BTA) guidelines (table 1) (12). Serum calcitonin was measured and fine needle aspiration (FNA) of the thyroid confluence was performed to help rule out MTC. Using BTA classification, cytology was in keeping with a Thy-2 sample, which maps directly to the American Bethesda Categories and means it was non-neoplastic (Table 2) (12).

Calcitonin was 3900pg/ml (normal range 0-4.8), CEA 4.6ug/L (normal range 0-3.8). She was reviewed in the clinic, by which time she had already been on prednisolone 10mg daily to try and stimulate her appetite. Whilst in clinic, she reported significant polydipsia and polyuria, and her serum blood glucose was 21mmol/L. She was admitted for urgent inpatient management of steroid-induced diabetes.

Whilst an inpatient, she was also referred for a 68Ga-DOTATATE PET/CT scan which showed multiple sites of progression with pleural and nodal disease (see figure 6). The finding was concerning of an upper right lobe lung primary with extensive right pleural and possibly solitary left pleural, nodal (above and below the diaphragm), and soft tissue (posterior to left psoas muscle ad inter left gluteal muscle) metastases.

It was decided that, considering the results of gluteal mass histology, thyroid nodule cytology and imaging, the most likely diagnosis was not MTC but that of a neuroendocrine lung neoplasm, grade 3. This patient deteriorated rapidly and died of complications before any further interventions were possible.
5. Discussion

CTN-secreting NENs are rare, with few reported cases in the last 20 years. Whilst small cell lung carcinomas (SCLC) are more commonly associated with ectopic CTN secretion, a review by Bondy et al. suggested that in 51% of cases it is secondary to SCLC, 20% of squamous cell, 33% to adenocarcinoma and 33% to large cell lung carcinomas (LCLC) (19). As patients with ectopic CTN secretion may not display overt clinical symptoms, they might not be tested for serum CTN and this may be one reason for the low number of reported cases. Another reason for the low number of reported cases may be that raised CTN is not associated with characteristic symptoms distinguishing this from other PNS. Reported symptoms associated with raised CTN could be diarrhoea, flushing, metabolic alkalosis with hypokalaemia, hypocalcaemia, hypomagnesaemia, hypophosphataemia and hyperglycaemia (3,20). Nozières et al. showed that only one third of the patients with significantly raised CTN concentration above 100ng/L had symptoms such as profuse diarrhoea and deranged electrolytes such as hypokalaemia, hypophosphataemia, hypocalcaemia and metabolic alkalosis (4). There are multiple other neuroendocrine neoplasms causing diarrhoea such as gastrinomas, VIPomas, glucagonomas, somatostatinomas and the carcinoid syndrome, as well as medullary thyroid cancer and hypercalcitoninaemia secreted from the pancreas causing Verner-Morrison syndrome (20). In the reported cases, when patients with CTN secreting lung NENs have clinical symptoms, there is usually co-secretion of other biologically-active substances, and it is these substances which most likely explain the symptoms rather than the raised CTN (2,3,5,7,20).

Evidence that the frequency of hypercalcitoninaemia may be higher than expected comes from Tsutsumi et al., who found 10 out of 45 SCLC patients were CTN immunoreactive, and 14 out of 32 patients with bronchial carcinoid had CTN immunoreactivity on histopathological examination (21). Interestingly, their immunohistochemical studies demonstrated that bronchial carcinoids appear to imitate fetal or neonatal lung in terms of
calcitonin/calcitonin-gene related peptide expression. However, it was not known whether these patients had raised serum CTN concentrations. A significant proportion of lung neoplasms from that study were tested histologically and appeared to have the ability to express CTN, albeit patients were more often clinically asymptomatic (21).

A summary of the study characteristics that were included in our systematic review are included in Table 3. It is important to note that the most insignificant studies were performed before 1995: manuscripts published after 1995 are mostly case reports or small case series. A possible explanation for this is the method CTN was tested in the past. The initial approach was using radioimmunoassay, which lacked sensitivity and specificity, and so this led to a two-sided immunoradiometric assay developed in the late 1980s (8). In the early 2000s there was movement to fluorescent and chemiluminescent tests, which were more accurate. Enzyme-linked immunoassay (ELISA) technique was used, but an issue with ELISA was heterophilic antibody interference, associated with false positives or higher than actual values (8). One of the latest developments is the electrochemiluminescence immunoassay (ECLIA), which allows for a prompt and accurate diagnosis (8). This may be a reason why when large cohorts of patients with various NENs are randomly screened for CTN concentrations, such as with Daskalakis et al. (2), the percentage of them with hypercalcitoninaemia is considerably less than several decades ago.

Coombes et al., Ellison et al. and Hillyard et al. published some of the earlier studies demonstrating that lung carcinomas can lead to ectopic secretion of CTN (22-24). Coombes et al. showed that, in 8 out of 11 patients with SCLC in their study, there was ectopic CTN secretion (22).

Silva et al. showed that 52% of their 61 patients had hypercalcitoninaemia (25). They also demonstrated that if the patient had a clinical response to treatment, this would be mirrored by a decrease in CTN concentration. Hansen et al. measured CTN concentrations
in 75 patients with SCLC and found elevated CTN in 48 patients (26). Multiple patients in
this study also had co-secretion of either ACTH or vasopressin (ADH). Hansen et al. found
that there was no correlation with CTN and stage of disease, meaning higher CTN
concentrations were not associated with more extensive disease (26).

Hansen et al. questioned whether previous studies reporting on the incidence of
hypercalcitonaemia in their cohorts was due to infiltrative bone disease (27). None of the
74 patients from their cohort had hypercalcaemia, albeit two thirds had hypercalcitonaemia.
They found that when comparing different stages of the disease, there was no significant
difference to CTN concentration, and that bone metastases did not lead to CTN elevations.
CTN concentrations were in the range expected for MTC. In another study, Hansen et al.
found that CTN concentration was not predicting response to treatment comparing
responders to non-responders (28).

Hansen et al. performed a detailed follow-up of patients with hypercalcitonaemia (29).
Their study had three arms and all patients in their study had SCLC. In the first arm, 6
patients with raised CTN concentrations had blood tests taken prior to their chemotherapy
which consisted of cyclophosphamide and vincristine. Blood samples were then repeated at
regular intervals over a week. 4 out of 6 patients had raised baseline CTN concentrations,
and in those 4 patients there was a significant decrease in CTN levels at one week following
treatment. The second arm had baseline blood tests prior to chemotherapy, 3-6 months
later, and then again if there was evidence of disease relapse: 11 patients in this arm had
baseline CTN concentrations exceeding 79pg/ml and tumour partial or complete response
to treatment. In this group, 9 of 11 patients who responded to treatment also had a
significant reduction in CTN. Eight of these 9 patients then had tumour relapse, with a
subsequent rise in CTN concentration. However, this rise was only moderate, albeit disease
symptoms were clinically significant, indicating that CTN was not a useful prognostic marker.
The results suggested that only in a small proportion of patients would CTN be of prognostic
value, but no consistent patient characteristics were identified. Only 3 patients with hypercalcitonaemia in remission were followed up to 18 months after treatment initiation. Their CTN concentrations had only been moderately increased at baseline and remained stable after 18 months follow up.

Gropp et al. used a higher pathological CTN cut off (\textgreater;125pg/ml), and abnormal results were observed in 26 out of 54 patients with SCLC. There was no positive or negative correlation to disease stage (30). CTN concentrations would decrease if there was a good response to treatment and rise in poor responders but findings were only numerically significant. In a study by Coombes et al., whilst higher baseline serum CTN values were associated with a poorer response to treatment, it was recommended that measuring serum CTN to predict response to treatment should be kept to a minimum (31).

Tabolli et al. reported a high incidence of hypercalcitonaemia, with 53.6\% of their 41 bronchogenic carcinomas showing a raised CTN, but unlike Gropp et al. they did not provide information regarding their histopathological characteristics (32). As concentrations were regularly increased in patients with malignant neoplasms, CTN was felt to be a useful marker.

Roberts et al. presented a case of a patient with hypercalcitonaemia and amylase co-secretion. The patient also had raised adrenocorticotrophic hormone (ACTH), raised growth hormone, and raised luteinising hormone (33). Sano et al. discuss a patient with lung carcinoid co-secreting somatostatin and CTN (34). A particularly rare case of ectopic co-secretion of 6 hormones including CTN from one tumour was reported by Monsieur et al. (17). Melanin production in MTC and lung carcinoid tumours leading to diagnostic uncertainty has been reported by Eagle et al. (35). Initially, the diagnosis was thought to be primary amelanotic choroidal melanoma with choroidal metastases. However, detailed investigations confirmed a primary lung carcinoid (35).
In a study of patients with untreated SCLC, Samuels et al. demonstrated no relationship between CTN concentration and disease stage or survival rate (36). On review of previous studies, they estimated that 25-66% of patients with SCLC have elevated CTN concentrations at the time of diagnosis; 71% of their 69 patients had elevated CTN, but the only significant result found was hypercalcitonaemia in liver metastases, with hypercalcitonaemia having a sensitivity of 100% but a specificity of only 41% and a positive predictive value of 40%. As with Hansen et al., there was no significant difference to CTN concentrations in case of metastatic bone disease (27).

Kelley et al. designed a study with 3 arms, including non-smokers without SCLC, smokers without SCLC, and smokers with SCLC (10). All but one of the 49 patients smoked in the SCLC group. They were able to demonstrate that in the two groups without SCLC, smoking appeared to moderately increase CTN. Kelley et al. also demonstrated in a murine animal model that air pollution or smoking increased the number of pulmonary neuroendocrine cells that were positive for CTN on immunohistochemical staining, and that smoking appeared to cause hyperplasia of the pulmonary neuroendocrine cells. In their human study, CTN concentrations were not correlated with severity of smoking. Interestingly, 6 patients with SLCL had negative staining for CTN on immunohistochemistry, but elevated serum CTN. Like in other cases of PNS with peripherally-raised hormone but negative staining, one theory for this may be that SCLC cells may have acquired the ability to secrete CTN but have not completely altered their machinery to express this histologically. It was concluded that the use of CTN was not a reliable marker for monitoring treatment response (10).

Interestingly, on immunohistochemical studies of 2 of the reported studies reported in Table 3, there was negative CTN tissue staining but raised serum levels, similar to the findings of Kelley et al. (10,11,20). Pratz et al. (20) hypothesised that large cell lung carcinoma (LCLC) cases they described co-secreted VIP and CTN. One theory was that LCLC tumours from their study were biologically behaving like a VIPoma, in which cells rapidly secrete CTN reaching
high serum concentrations, and so may not be seen expressed within the tumour cells. An alternative theory was that the neoplasm secretes an as yet unknown substance which stimulates CTN secretion from C cells. Whilst there can be other causes of hypercalcitonaemia (7,8,10), these would not induce CTN elevation as such reported by Pratz et al. (20).

Coners et al. reported the first case of SCLC co-secreting ACTH and CTN (3). Cvijovic et al. presented a patient with multinodular goitre, neck lymphadenopathy, raised CTN and raised carcinoembryonic antigen (CEA), who was referred to them initially with the diagnosis of MTC (7). Surgical excision of the lymph node showed this to be a metastasis from a neuroendocrine neoplasm, with bronchoscopy confirming the diagnosis (7).

Similarly, Vahidi et al. report a case of suspected MTC but with an incidental lung lesion seen on a chest x-ray and biopsy suggesting either MTC or other NEN. Both cases by Cvijovic et al. and Vahidi et al. are similar to our case as thyroid FNA was required to help rule out MTC (6,7).

Daskalakis et al. performed a large retrospective study of more than 700 patients with NENs to describe the incidence of endocrine paraneoplastic syndromes (2). Only 4 patients were found to have hypercalcitonaemia, but the study included patients with multiple NEN sites not just originating from the lung. One of these patients was documented as having a lung carcinoid. All 4 patients had stage IV disease, and all 4 were described having concurrently other endocrine PNS with hypercalcitonaemia. This study highlights the rarity of lung NENs secreting CTN (2).

Machens et al. and Hansen et al., focused on the use of CTN stimulation tests to look at whether CTN secreting NENs can be distinguished from MTC based on response to calcium or pentagastrin tests. Whilst Machens et al. suggested that MTC tends to be associated with a doubling CTN concentration following stimulation, Hansen et al. warned that there can
still be a significant CTN rise in lung NENs, and that high CTN response to stimulation is not
pathognomonic for MTC (9, 37). 54 of the 79 patients had hypercalcitonaemia prior to
pentagastrin test, with 25% of them having CTN concentrations expected of MTC.

In the largest recent study of CTN secreting NENs, Nozières et al. reviewed the data of 17
patients with lung NENs secreting CTN (5). Nine of these patients had high CTN
concentrations over 100ng/l at diagnosis. Whilst Nozières et al. did not demonstrate an
association between CTN concentrations and prognosis, patients whose CTN concentration
was >100ng/l had higher grade neoplasms. They suggest testing for CTN in patients with
foregut NENs and diarrhoea (5).

6. Conclusions

This work highlights the importance of considering differentials to MTC when presented with
thyroid pathology and hypercalcitonaemia, and that although raised serum calcitonin
suggests MTC, it is not pathognomonic. Our review of the literature highlights conflicting
results when interpreting CTN role in predicting biological behaviour, response to treatment
or overall survival rates in cases of patients with ectopic hypercalcitonaemia to lung NENs.
The interpretation of elevated serum calcitonin is still a matter of debate given the many
confounding factors, variety of assays with limited efficacy and different cut-offs. We
propose a thorough clinical evaluation of all patients presenting with elevated CTN
concentration followed by multidisciplinary discussion when planning investigations and
therapy to avoid misdiagnosis of ectopic CTN sources of secretion.

### U grading of thyroid nodules

| U1         | U2                   | U3                        | U4           | U5         |
|------------|----------------------|---------------------------|--------------|------------|
| normal     | benign               | indeterminat/equivocal    | suspicious   | malignant  |
| Normal     | Halo                 | Homogenous                | Solid        | Hypo-echoic|
| thyroid    | Iso-echoic or mildly | Hyper-echoic              | Hypo-echoic  | Lobulated  |
| tissue     | hyperechoic          | solid, halo (follicular)  | very hypo-echoic | irregular |
| Cystic change ± ring | lesion | Disrupted peripheral outline | calcification | Micro-calcific. |
| Down sign micro-cystic | Equivocal ecchogenic foci | Cystic change mixed/lobulated outline | Globular | |
| Peripheral vascularity | central vascularity | Intra-nodular vascularity | Shape (taller > wide) | Characteristic associated lymphadenopathy |

| No follow-up | No follow-up required | **FNAC** | **FNAC** | **FNAC** |
|--------------|-----------------------|----------|----------|----------|
| Required     | - routine FNAC not recommended unless high clinical suspicion of thyroid cancer |

FNAC = fine needle aspiration cytology

Table 1: U grading of thyroid nodules based on ultrasound imaging (18)
### Thyroid FNAC diagnostic categories

| Thy1 | Thy2 | Thy3 | Thy4 | Thy5 |
|------|------|------|------|------|
|      |      | Thy 3F | Thy 3A |      |
| Non-diagnostic | Non-diagnostic | Follicular lesion | Atypia present | Suspicious of thyroid cancer | Diagnostic of thyroid cancer |
| Neoplastic | e.g. colloid nodule or thyroiditis | Repeat FNAC | No follow-up if no suspicious US features and no clinical suspicion of thyroid cancer | If second Thy 3 A thyroidectomy in cytology obtained, lesion >4cm where incidence of malignancy is higher | Repeat ultrasound and FNAC discussion at MDT and investigations for staging, where indicated | Consider total hemithyroidectomy if second Thy 3 A, hemithyroidectomy further if investigations considered diagnostic, hemithyroidectomy Total thyroidectomy ± node clearance in appropriate high risk patients |
| Repeat FNAC | Diagnostic | Repeat ultrasound | Discuss at MDT | Discuss at MDT |
| e.g. colloid nodule or thyroiditis | Consider total | If second Thy 3 A thyroidectomy in cytology obtained, lesion >4cm where incidence of malignancy is higher | Repeat ultrasound and FNAC discussion at MDT and investigations for staging, where indicated | Consider total hemithyroidectomy if second Thy 3 A, hemithyroidectomy further if investigations considered diagnostic, hemithyroidectomy Total thyroidectomy ± node clearance in appropriate high risk patients |

*FNAC = fine needle aspiration cytology*

| Study | Country | Type of neoplasm | Study design | Follow-up (Months) | Sample size (n) | Calcitonin value (ng/L) | Symptomatic calcitonaemia | Assessment of outcome | NOS Star Award |
|-------|---------|------------------|--------------|-------------------|----------------|------------------------|--------------------------|------------------------|-----------------|
| Coners et al 2011 (3) | USA | SCLC | Case report | Died after 1st cycle of treatment | 1 | 81.8 | Diarrhoea thought not to be due to CTN | Somatostatin, cisplatin and etoposide saw moderate improvement to CTN concentrations, but patient deteriorated and died after 1st cycle of treatment | N/A |
| C vijovic et al 2013 (6) | Serbia | LCLC | Case report | Patient died after 7th cycle of treatment | 1 | 260 | No | 6 cycles of cisplatin and etoposide saw moderate improvement to CTN concentrations. One cycle of Peptide Receptor Radionuclide Therapy, but patient deteriorated and died | N/A |
| Nozières et al 2015 (4) | France | Study does not specify type, 4 out of 17 were documented as carcinoid | Retrospective | 5.6 years | 176 | >100 | One third of the patients with CTN >100pg/ml were potentially symptomatic | 8 out of 11 patients who were followed up had highest CTN concentration before death. 4 of these 11 patients had lung neoplasms, all which carcinoid. The trend towards poor survival if high CTN was not significant. No correlation with CTN and staging. | 7 |
| Vahidi et al 2018 (5) | USA | Atypical carcinoid | Case report | Not discussed | 1 | 5900 | No | Important to consider differentials, in case of unnecessary thyroidectomies | N/A |
| Daskalakis et al 2018 (1) | Sweden | Carcinoid | Retrospective | Mean follow up 89.6 months | 834 | Unknown but had to be >10 to be included in study | Potentially, but could be explained by short colonic transit times | All 4 patients with raised CTN had disseminated disease at diagnosis. All 4 were described together with another endocrine PNS. | 8 |

SCLC= small cell lung carcinoma, CTN= calcitonin, LCLC=large cell lung carcinoma, MTC=medullary thyroid carcinoma,
