Duality of Schramm-Loewner Evolutions

Julien Dubédat*

February 2, 2008

Abstract

In this note, we prove a version of the conjectured duality for Schramm-Loewner Evolutions, by establishing exact identities in distribution between some boundary arcs of chordal SLE_κ, κ > 4, and appropriate versions of SLE_\hat{\kappa}, \hat{\kappa} = 16/\kappa.

1 Introduction

Schramm-Loewner Evolutions (or SLE), introduced by Schramm in 1999, are probability distributions, parameterized by κ > 0 on non-self traversing curves (the trace) connecting two boundary points in a planar, simply connected domain. They are characterized by a conformal invariance condition and a domain Markov property. See [6, 15] for general SLE background.

The geometric properties of the trace vary with the parameter κ. In particular, when κ ≤ 4, the trace is a.s. a simple curve; this is no longer the case if κ > 4 ([11]). The trace stopped at some finite time is then distinct from its boundary. The duality conjecture for SLE, roughly stated, is that a boundary arc of SLE_κ is locally absolutely continuous w.r.t. to (some version) of SLE_\hat{\kappa}, \hat{\kappa} = 16/\kappa. This was suggested by Duplantier.

In the case (κ, \hat{\kappa}) = (8, 2), this follows from the exact combinatorial relation between Loop-Erased Random Walks and Uniform Spanning Trees and the identification of their scaling limits in terms of SLE ([7]). In the case (κ, \hat{\kappa}) = (6, 8/3), it follows from the locality/restriction framework ([5]). An approach based on a relation with the free field has been proposed by Sheffield.

A precise duality conjecture is stated in [1] and elaborated on in [3]; we prove slightly different versions here. These involve variants of SLE_κ: the SLE_κ(\rho) processes (\rho = \rho_1, \ldots, \rho_n). They satisfy a domain Markov property when keeping track of n marked points z_1, \ldots, z_n (in addition of the origin and the target of chordal SLE). The influence of z_i on the SLE trace is quantified by the real parameter \rho_i; this influence is attractive for \rho_i > 0 and repulsive for \rho_i < 0.

Let us consider a chordal SLE in the upper half-plane \mathbb{H}, going from 0 to infinity. In the phase 4 < κ < 8, a boundary point, say 1, is “swallowed”, i.e., gets disconnected from infinity by the trace at a random time \tau_1 when the trace hits some point in (1, \infty). The boundary arc straddling 1 is the boundary arc seen by 1 at time \tau_1-

Theorem 1. Consider a chordal SLE_κ in (\mathbb{H}, 0, \infty), 4 < κ < 8; let D be the leftmost visited point on (1, \infty). Conditionally on D, the boundary arc straddling 1 is distributed as an SLE_\hat{\kappa}(-\hat{\kappa}/2, \hat{\kappa} - 4, \hat{\kappa} - 2) in (\mathbb{H}, D, \infty, 0, 1, D^+), stopped when it hits (0, 1).

In the phase κ ≥ 8, a.s. every point in \mathbb{H} is visited by the trace. We isolate a boundary arc in a different way. Let G be the leftmost point on (−∞, 0) visited by the trace before \tau_1. We consider the boundary of

*Partially supported by NSF grant DMS0804314
The distributions of $D$ and $G$ are well known and easy to derive.

In [3], it is shown that duality shares common features with reversibility and the question of defining multiple SLE strands in a common domain. This local commutation property states that two SLE strands can be grown in a domain to a positive size, in a way that does not depend on the order in which the SLE’s are growing. Such systems of commuting SLE’s are classified in [3]; in particular, two versions of SLE, $\text{SLE}_\kappa$, can commute only if $\hat{\kappa} \in \{\kappa, 16/\kappa\}$.

In [16], Zhan proves reversibility of chordal SLE, $\kappa \leq 4$, i.e. that the range of the trace of an SLE, $\gamma$, in $D$ going from $x$ to $y$ has the same distribution as the range of the trace of SLE going from $y$ to $x$ in $D$. This was previously known for $\kappa \in \{2, 8/3, 4, 6, 8\}$. The argument involves a sequence of coupling of an $\text{SLE}_\kappa(D, x, y)$ with an $\text{SLE}_\kappa(D, y, x)$, such that each coupling in the sequence is absolutely continuous w.r.t. the trivial (independent) coupling, and the limiting coupling is exact (the ranges of the two traces are identical).

Let $\gamma, \hat{\gamma}$ be traces of two SLE’s satisfying the local commutation condition. Then, for $U, V$ disjoint open subsets of the domain, one has a coupling of $(\gamma, \hat{\gamma})$ which is “correct” on the time set $\{(s, t) : s \leq \tau, t \leq \hat{\tau}\}$, where $\tau, \hat{\tau}$ are stopping times for the two SLE’s, such that $\gamma \cap U, \hat{\gamma} \cap V$. We construct a coupling of $(\gamma, \hat{\gamma})$, which is “correct” on the time set $\{(s, t) : \gamma_{[0,s]} \cap \hat{\gamma}_{[0,t]} = \emptyset\}$. See Theorem [3] for a precise statement.

The duality identities follow from applying Theorem [3] to appropriate pairs of commuting SLE’s, together with some a priori geometric information on the traces. Plainly, many identities may be generated in this fashion.

The article is organized as follows. Section 2 recalls some absolute continuity properties of chordal SLE. Local commutation is discussed in Section 3. Maximal couplings of commuting SLE’s are constructed in Section 4. Geometric consequences (in particular duality) are drawn in Section 5. Some technical lemmas are postponed to Section 6.

Acknowledgments. I wish to thank Greg Lawler for comments on an earlier version of this article and Oded Schramm for useful conversations.

2 Absolute continuity for chordal SLE

In this section we consider some absolute continuity properties of chordal SLE, mostly based on [5]. Chordal SLE will also serve as a reference measure for variants we will study later.

We adopt the following notation: $c = (D, x, y)$ is a configuration where $D$ is a simply connected domain and $x, y$ are distinct boundary points. Unless there is an ambiguity, the configuration is simply denoted by $D$. The chordal $\text{SLE}_\kappa$ measure on $c = (D, x, y)$ is denoted by $\mu_c$ ($\kappa$ is fixed). It is seen as a measure on Loewner chains up to increasing time change; or as a configuration-valued continuous process (up to time change); or as a measure on non self-traversing paths ([11]). This path (the SLE “trace”) is denoted by $\gamma$, while the hull it generates is denoted by $K$. Let $U$ be a subdomain of $D$, agreeing with $D$ in a neighbourhood of $x$, and not containing $y$ on its boundary. Then $\mu_U^D$ denotes the measure on paths induced by chordal SLE starting from $x$ and stopped on exiting $U$; this happens at a random time $\tau$, at which the hull is $K_\tau$, the tip of the trace is $\gamma_\tau$, and the configuration $c_\tau$ is $(D_\tau = D \setminus K_\tau, \gamma_\tau, y)$. More generally, for $\tau$ a stopping time, $\gamma_\tau$ denotes the trace stopped at $\tau$ (ie the process up to time $\tau$), $\mu^D_\tau$ the measure induced by stopping at $\tau$. We will use $\gamma$ to denote both the trace as a process and as a subset of $\bar{D}$ (the range of the process).
Later on, we will use tightness conditions, so we shall review some technical points now. Let \((D, x, y)\) be a (bounded) configuration, \(K\) a hull such that \((D \setminus K, x', y')\) is a configuration for some \(x' \in \partial K\). By the Riemann mapping theorem, there is a conformal equivalence \(\phi_K : D \setminus K \to D\); one can specify it uniquely by requiring its 2-jet at \(y\) to be trivial \((\phi_K(y) = y, \phi_K'(y) = 1, \phi_K''(y) = 0\) if \(\phi_K\) extends smoothly at \(y\); this condition is coordinate independent, so one can first “straighten” the boundary at \(y\). One defines a topology on hulls as follows: \((K_n)\) converges to \(K\) if \(\phi_{K_n}\) converges to \(\phi_K\) uniformly on compact sets of \(\overline{D}\) that are at positive distance of \(K\). This is a version of Carathéodory convergence. A topology on chains \((K_t)_{t \geq 0}\) is given by the condition: \((K^t)\) converges to \((K)\) if for all \(T > 0, K'\) a compact set of \(\overline{D}\) at positive distance of \(K_T\), \(\phi_{K^t} \to \phi_K\) uniformly on \([0, T] \times K'\). Then the Loewner equation maps continuously \(C([0, T], \mathbb{R})\) (with the usual topology of uniform convergence on compact sets) to the space of chains endowed with this topology ([4] Section 4.7). Thus the induced measure on chains is a Radon measure. From [11], we know that the chain is a.s. generated by a continuous non self-traversing path \(\gamma\). For clarity, we will think of SLE as a measure on such paths, with the topology on chains described above.

To express densities, we need to define some conformal invariants. Let \((D, x, y)\) be a configuration, \(z_x, z_y\) analytic local coordinates at the boundary \((z_x\) mapping a neighbourhood of \(x\) in \(D\) to the neighbourhood of \(0\) in the upper semidisk). The Poisson excursion kernel is defined as

\[
H_D(x, y) = \lim_{x \to z_x, y \to z_y} \frac{G_D(X, Y)}{3(z_x(X))3(z_y(Y))}
\]

where \(G_D\) is the Green function in \(D\) (with Dirichlet boundary conditions); this depends on the choice of \(z_x\) (or \(z_y\)) as a (real) 1-form. If \(D\) and \(D'\) agree in a neighbourhood of \(x\), we choose the same local coordinate \(z_x\), so that \(H_{D'}(x, y')/H_D(x, y)\) does not depend on a choice of local coordinate at \(x\). Similarly for \(i, j = 1, 2\), consider configurations \((D_{ij}, x_i, y_j)\) such that \(D_{ij}\) agrees with \(D_{i,3-j}\) in a neighbourhood of \(x_i\) and with \(D_{3-i,j}\) in a neighbourhood of \(y_j\). Then the ratio:

\[
\frac{H_{D_{11}}(x_1, y_1)H_{D_{22}}(x_2, y_2)}{H_{D_{12}}(x_1, y_2)H_{D_{21}}(x_2, y_1)}
\]

is defined independently of any (coherent) choice of local coordinates. To simplify the notation, if \(c = (D, x, y)\) is a configuration, we set \(H(c) = H_D(x, y)\).

There is a \(\sigma\)-finite measure \(\mu^{loop}\) on unrooted loops in \(\mathbb{C}\), the Brownian loop measure ([5] [8]). As in [4], let us denote

\[
m(D; K, K') = \mu^{loop}\{\delta : \delta \subset D, \delta \cap K \neq \emptyset, \delta \cap K' \neq \emptyset\}.
\]

In accordance with [3], set \(\alpha = \alpha_c = \frac{6-\kappa}{2\kappa}, \lambda = \lambda_c = \frac{(6-\kappa)(8-3\kappa)}{2\kappa}\).

**Proposition 3.** If \(c = (D, x, y)\) and \(c' = (D', x', y')\) are configurations agreeing in a neighbourhood \(U\) of \(x, \partial U \cap \partial D = \partial U \cap \partial D'\) a connected arc containing \(x\) at positive distance of \(y, y'\), then \(\mu^L_c\) and \(\mu^L_{c'}\) are mutually absolutely continuous, with density

\[
\frac{\frac{d\mu^L_U}{d\mu^L_{c'}}(\gamma)}{\exp(-\lambda m(D; K, D' \setminus D) + \lambda m(D'; K, D' \setminus D))}
\]

uniformly bounded above and below.

**Proof.** We will reduce the statement to two known cases.

1. Assume that \(D = D'\). Then the statement follows from Lemma 3.2 in [4]; see also [13]. More precisely, consider the following situation: \(\mathbb{H}\) is the upper half-plane, three boundary points \(x, y, y'\) are marked; \(K\) is a hull around \(x, x'\) its tip, \(\phi\) a conformal equivalence \(\mathbb{H} \setminus K \to \mathbb{H}\). Then \(H_{\mathbb{H}}(x, y) = (x - y)^{-2}\), \(H_{\mathbb{H}}(x, y') = (x - y')^{-2}\), computing in the natural local coordinate. It follows that \(H_{\mathbb{H} \setminus K}(x', y) = \frac{\phi'(y)}{(\phi(y) - \phi(x'))^2}\).
\[ H_{\mathbb{H}\setminus K}(x', y') = \frac{\phi'(y')}{\phi(y') - \phi(x')}^2 \text{ for an appropriate (common) local coordinate at } x'. \] Then the ratio
\[ \frac{H_{\mathbb{H}\setminus K}(x', y')}{H_{\mathbb{H}\setminus K}(x, y)} = \frac{\phi'(y')}{\phi(y') - \phi(x')}^2 \frac{\phi'(y)}{\phi(y') - \phi(x')} \]
is independent of (coherent) choices. One concludes by identifying the density of an SLE_κ(\mathbb{H}, x, y) and an SLE_κ(\mathbb{H}, x, y') with respect to the common reference measure SLE_κ(\mathbb{H}, x, \infty).

2. Assume that \( D' \subset D, D' \) and \( D \) agree in a neighbourhood of \( y = y' \). Then the statement is a rephrasing of Proposition 5.3 in [3].

3. The general case reduces to 1,2 as follows. Let \( y'' \) be a point on the connected boundary arc of \( x \) in \( \partial D \cap \partial D' \), which is not on \( \partial U \); and \( V \) the connected component of \( D \cap D' \) having \( x \) on its boundary. Then apply 1 to go from \( (D, x, y) \) to \( (D, x, y') \); then 2 to go from \( (D, x, y') \) to \( (V, x, y'') \); then 1 to go from \( (V, x, y'') \) to \( (D', x, y') \); then 2 to go from \( (D', x, y') \) to \( (D', x, y') \). Cancellations occur due to the “inclusion exclusion” form of the ratios \( (H(c'_x)H(c)/H(c_x))H(c') \).

For a general bound on densities, see Lemma [4].

3. Local commutation

3.1 Reversibility

Following the discussion in Section 2.1 of [3], we phrase and then check a necessary condition for reversibility.

Consider a configuration \( c = c_{0,0} = (D, x, y), \gamma \) an SLE from \( x \) to \( y \) and \( \hat{\gamma} \) an SLE from \( y \) to \( x \). Denote \( c_{s,t} = (D \setminus (K_s \cup K_t), \gamma_s, \hat{\gamma}_t) \). Let \( U, \hat{U} \) be disjoint neighbourhoods of \( x, y \) respectively; \( \tau, \hat{\tau} \) denote first exits of \( U, \hat{U} \) by \( \gamma, \hat{\gamma} \) respectively. Assume that \( \gamma, \hat{\gamma} \) can be coupled so that one is the reversal of the other. Then an application of the Markov property for \( \gamma, \hat{\gamma} \) shows that the distribution of \( \gamma^\tau \) conditional on \( \hat{\gamma}^\tau \) is (stopped) SLE in \( c_{0,\tau} = (D \setminus K_{\tau}, x, \hat{\gamma}_{\tau}) \). Symmetrically, the conditional distribution of \( \hat{\gamma}^\tau \) given \( \gamma^\tau \) is SLE in \( c_{\tau,0} = (D \setminus K_{\tau}, \gamma_{\tau}, y) \). By integration, this gives the identity of measures:

\[ \int \hat{f}(\hat{\gamma}^\tau) \int f(\gamma^\tau) d\mu_{c_{\tau,0}}(\gamma^\tau) d\mu_{\hat{c}_{\tau,0}}(\hat{\gamma}^\tau) = \int \hat{f}(\hat{\gamma}^\tau) \int f(\gamma^\tau) d\mu_{\hat{c}_{\tau,0}}(\hat{\gamma}^\tau) d\mu_{c_{\tau,0}}(\gamma^\tau) \tag{3.1} \]

for arbitrary positive Borel functions \( f, \hat{f} \). This is the local commutation condition studied in [3]. Disintegrating and inserting densities (that exist from absolute continuity properties) yields the condition:

\[ \left( \frac{d\mu_{c_{\tau,0}}}{d\mu_{\hat{c}_{\tau,0}}} \right)(\gamma^\tau) = \left( \frac{d\mu_{\hat{c}_{\tau,0}}}{d\mu_{c_{\tau,0}}} \right)(\hat{\gamma}^\tau) \tag{3.2} \]

almost everywhere in \( \gamma^\tau, \hat{\gamma}^\tau \). This is an identity between two (continuous) functions of the paths \( \gamma, \hat{\gamma} \). From the above results on absolute continuity of SLE (Proposition [3], we see that both sides are indeed equal, and their common value is the explicit quantity:

\[ \ell_D(\gamma^\tau, \hat{\gamma}^\tau) = \left( \frac{H(c_{\tau,0})H(c)}{H(c_{\tau,0})H(c_{\tau,0})} \right)^{\alpha} \exp(-\lambda m(D; K_{\tau}, \hat{K}_{\hat{\tau}})) \tag{3.3} \]

which is manifestly symmetric in \( \gamma^\tau, \hat{\gamma}^\tau \). (We use \( \ell \) for likelihood ratio, somewhat abusively.)

Using the expression of \( \ell \) as Radon-Nikodym derivatives of probability measures, we see that:

\[ \int \ell_D(\gamma^\tau, \hat{\gamma}^\tau) d\mu_{c_{\tau,0}}(\hat{\gamma}^\tau) = \int d\mu_{c_{\tau,0}}(\hat{\gamma}^\tau) = 1 \quad \forall \gamma^\tau \]

\[ \int \ell_D(\gamma^\tau, \hat{\gamma}^\tau) d\mu_{c_{\tau,0}}(\gamma^\tau) = \int d\mu_{c_{\tau,0}}(\gamma^\tau) = 1 \quad \forall \hat{\gamma}^\tau \tag{3.4} \]
This also applies to any pair of stopping times \( \sigma, \hat{\sigma} \) dominated by \( \tau, \hat{\tau} \) (ie \( \sigma \) is a stopping time for \( \gamma \) such that \( \sigma \leq \tau \) a.s.).

Such local commutation identities (without relying on explicit densities) are proved in greater generality in \cite{3} under an infinitesimal commutation condition, which is easily checked in the present case.

Let us also point out a (deterministic) tower property, dictated by compatibility with the SLE Markov property. Let \((D, x, y)\) be a domain, \((K_s)\) a Loewner chain growing at \(x\) (with trace \(\gamma_s\)), and \((\hat{K}_t)\) a Loewner chain growing at \(x\) (with trace \(\hat{\gamma}_t\)). Let \(c_{s,t} = (D \setminus (K_s \cup \hat{K}_t), \gamma_s, \hat{\gamma}_t)\). Let us denote, for \(0 \leq s_1 \leq s_2, 0 \leq t_1 \leq t_2:\)

\[
\ell_{s_1,t_1}^{s_2,t_2} = \ell_{c_{s_1,t_1}}(\gamma_{s_2}, \hat{\gamma}_{t_2})
\]

Then, for \(0 \leq s_1 \leq s_2 \leq s_3, 0 \leq t_1 \leq t_2 \leq t_3:\)

\[
\ell_{s_1,t_1}^{s_2,t_2} \ell_{s_2,t_2}^{s_3,t_2} \ell_{s_1,t_1}^{s_3,t_2} = \ell_{s_1,t_1}^{s_3,t_3} \ell_{s_1,t_1}^{s_2,t_2} \ell_{s_2,t_2}^{s_3,t_3} = \ell_{s_1,t_1}^{s_2,t_2} \ell_{s_2,t_2}^{s_3,t_3}
\]

For fixed \(\gamma\), the first relation has to hold a.e. in \(\gamma\) to ensure compatibility of \((3.3)\) with the Markov property of \(\gamma\); the second relation corresponds to the Markov property of \(\hat{\gamma}\). Alternatively, this can be checked directly from the explicit expression \((3.3)\), by telescopic cancellations and the restriction property of the loop measure \(\mu_{\text{loop}}\) \((\mathbb{S})\).

### 3.2 The general case

We now move to the general case (in simply connected domains) of local commutation, following Theorem 7.1 of \cite{3}, which we rephrase in the present context.

A configuration consists of a simply connected domain \(D\) with marked points: \(c = (D, z_0, z_1, \ldots, z_n, z_{n+1})\); the marked points are distinct and in some prescribed order on the boundary. The question is to classify pairs of SLE (with the SLE Markov property relatively to these configurations), one growing at \(z_0\) (hulls \((K_s)\), trace \(\gamma\)), one at \(z_{n+1}\) (hulls \((\hat{K}_t)\), trace \(\hat{\gamma}\)), that satisfy local commutation \((3.1), (3.2)\). As before, we denote \(c_{s,t} = (D_{s,t} = D \setminus (K_s \cup \hat{K}_t), \gamma_s, z_1, \ldots, z_n, \hat{\gamma}_t)\) when this is still a configuration (ie before swallowing of any marked point).

We take as reference measures a chordal SLE\(_k\) from \(z_0\) to \(z\), and a chordal SLE\(_\hat{k}\) from \(z_{n+1}\) to \(z\), where \(z\) is another marked boundary point, used solely for normalization. Then:

**Theorem 4 \((\mathbb{3})\).** Local commutation is satisfied iff: \(\hat{k} \in \{k, 16/k\}\) and there exists a conformally invariant function \(\psi\) on the configuration space and exponents \(\nu_{ij}\) such that \(\sum_{j=1}^{n+1} \nu_{0,j} = \alpha_k\), \(\sum_{i=0}^{n} \nu_{i,n+1} = \alpha_{\hat{k}}\), and if

\[
Z(c) = \psi(c) \prod_{0 \leq i < j \leq n+1} H_D(z_i, z_j)^{\nu_{ij}}
\]

and

\[
M_s = H_c(z_0, z)^{-\alpha_k} Z(c_{s,0})
\]

\[
\hat{M}_t = H_c(z_{n+1}, z)^{-\alpha_{\hat{k}}} Z(c_{0,t})
\]

then \((M_s)\) is a local martingale for SLE\(_k\)(\(D, z_0, z\)), \((\hat{M}_t)\) is a local martingale for SLE\(_\hat{k}\)(\(D, z_{n+1}, z\)); these martingales are the densities of the commuting SLE’s w.r.t. the reference chordal SLE measures, up to swallowing of a marked point.

In the theorem, notice that \(M_s = H_c(z_0, z)^{-\alpha_k} Z(c_{s,0})\) is defined via a choice of local coordinates at \(z, z_1, \ldots, z_{n+1}\), but not at \(z_0\), where the evolution occurs (the choice of local coordinates is arbitrary but fixed under evolution).
A good example of the situation is the following: \( \hat{\kappa} = \kappa = 6 \), with four marked points \((z_0, z_1, z_2, z_3)\), \( \psi \) the probability that there is a percolation crossing from \((xy)\) to \((z_1 z_2)\).

The absolute continuity properties of these SLE’s reduce to that of chordal SLE as in Lemma \([13]\) let \( Z(c) = \psi(c) \prod_{i<j} H_D(z_i, z_j)^{\nu_{ij}} \) (this depends on local coordinates at the \( z_i \)’s; appropriate ratios will not depend on coherent choices). Then we have

\[
\ell_D(\gamma^\tau, \hat{\gamma}^\tau) = \left( \frac{Z(c, \hat{\tau})Z(c_0, \hat{\tau})}{Z(c, 0)Z(c_0, 0)} \right) \exp(-\lambda m(D; K, \hat{\kappa}))
\]

where, if \( \mu_c, \mu_{c'} \) denote the two commuting SLE measures, \( \tau, \hat{\tau} \) stopping times preceding swallowing of any marked point,

\[
\ell_D(\gamma^\tau, \hat{\gamma}^\tau) = \left( \frac{d\mu^\tau_c}{d\mu^\tau_{c'}} \right) \left( \frac{d\mu^\hat{\tau}_c}{d\mu^\hat{\tau}_{c'}} \right) \left( \gamma^\tau \right).
\]

Notice that when \( \hat{\kappa} \in \{\kappa, 16/\kappa\} \), \( \lambda_\kappa = \lambda_{\hat{\kappa}} \). From compatibility with the SLE Markov property, or directly from the expression \([4, 6]\), we still have the tower property (see \([3]\)).

The definition of \( Z \) involves 1-jets of local coordinates at marked points; one could imagine more complicated dependences, say on \( k \)-jets at marked points; this is ruled out by the theorem. The situation in other (non simply connected) topologies is quite involved, though an important part of the analysis carries through (see \([3]\)). For \( n \) SLE’s in a simply connected domain, the local commutation relation for the system of \( n \) SLE’s reduces to \( n^{(n-1)} \) pairwise commutation conditions.

An easy way to generate systems of commuting SLE’s is to look for partition functions in the simple form \( Z(c) = \prod_{i<j} H_D(z_i, z_j)^{\nu_{ij}} \). For an admissible choice of exponents \( \nu_{ij} \), this corresponds to an SLE\(_n(\hat{\rho}, \hat{\rho})\) in \((\mathbb{H}, z_0, \ldots, z_{n+1})\) with \( \rho_i = -2\kappa \nu_{0i}, i = 1 \ldots n; \rho = \rho_{n+1} = -2\kappa \nu_{0, n+1} \). Similarly, the other SLE is an SLE\(_n(\hat{\rho}, \hat{\rho})\) with \( \hat{\rho} = \hat{\rho}_0 = -2\hat{\kappa} \nu_{0, n+1} \), and \( \hat{\rho}_i = -2\hat{\kappa} \nu_{i, n+1} \).

This situation is studied in \([3]\), Section 3.2. The following systems are found to solve the local commutation condition:

1. \( \kappa = \hat{\kappa}; \rho = \hat{\rho} = \kappa = 6; \rho_i = \hat{\rho}_i = 0 \) (two chordal SLE’s aiming at each other, the reversibility setup)
2. \( \kappa = \hat{\kappa}; \rho = \hat{\rho} = 2; \rho_i = \hat{\rho}_i, \rho + \sum_i \rho_i = \kappa = 6 \) (\( n-1 \) arbitrary parameters)
3. \( \kappa\hat{\kappa} = 16, \rho = -\kappa/2, \hat{\rho} = -\hat{\kappa}/4, \hat{\rho}_i = -1(\kappa/4)\rho_i = -(4/\kappa)\rho_i, \rho + \sum_i \rho_i = \kappa = 6 \) (\( n-1 \) arbitrary parameters)

In these cases, we have the following expressions for the common partition function (see Lemma \([12]\)):

\[
Z(c) = H(z_0, z_{n+1})^{-\frac{6\kappa}{4\kappa}}\prod_i H(z_0, z_i)^{-\frac{\rho_i}{2\kappa}} H(z_{n+1}, z_i)^{-\frac{\hat{\rho}_i}{2\kappa}} H(z_i, z_j)^{-\frac{\rho_i \hat{\rho}_j}{4\kappa}}
\]

In the third case \( \kappa\hat{\kappa} = 16 \), notice that \( -\frac{\rho_i}{2\kappa} = -\frac{\hat{\rho}_i}{4\kappa} = -\frac{\hat{\rho}_i \hat{\rho}_j}{4\kappa} \).

Another explicit situation is when four points are marked, so that there is a single cross-ratio. Consider a configuration \( c = (D, x, y, z_1, z_2) \), the marked points in some prescribed order. Let \( \nu \) be a parameter and \( \beta \) a solution of the quadratic equation \( \frac{6-n}{2} \beta (\beta - 1) + 2/\beta = 2\nu \). Define a partition function

\[
Z(c) = H_D(x, y)^{\frac{6-n}{2\nu}} H_D(z_1, z_2)^{\nu} \psi(u)
\]
where \( u \) is the cross-ratio \( u = \frac{(z_2 - x)(z_3 - y)}{(y - x)(z_2 - z_1)} \) (in the upper half-plane) and

\[
\psi(u) = (u(1 - u))^{\beta} 2F_1(2\beta, 2\beta + \frac{8}{\kappa} - 1; 2\beta + \frac{4}{\kappa}; u)
\]

where \( 2F_1 \) designates a solution of the hypergeometric equation with parameters \( 2\beta, \ldots \) (this equation is invariant under \( u \leftrightarrow 1 - u \)). If the solution is chosen so that it is positive on the configuration space, then a computation shows that \( Z \) satisfies the condition of the theorem and drives two locally commuting SLE’s starting from \( x, y \). This covers for instance the following situations: a chordal SLE\(_{\kappa} \) from \( x \) to \( y \) conditioned not to intersect the interval \([z_1, z_2] \), \( 4 < \kappa < 8 \); a chordal SLE\(_{8/3} \) from \( x \) to \( y \) conditioned not to intersect a restriction measure (with exponent \( \nu \)) from \( z_1 \) to \( z_2 \); and the marginal of a system of two SLE strands \( x \leftrightarrow y, z_1 \leftrightarrow z_2 \) ([2], Section 4.1; this corresponds to \( \nu = \alpha_\kappa \)).

## 4 Coupling

Let \( c = (D, z_0, z_1, \ldots, z_n, z_{n+1}) \) be a configuration, where \( D \) is a simply connected, bounded domain with \( n + 2 \) distinct marked points on the boundary in some prescribed order. We consider a system of two SLE’s satisfying local commutation, one originating at \( z_0 \), the other at \( z_{n+1} \). These two SLE’s have the SLE Markov property for domains with \( n + 2 \) marked points. The first one is absolutely continuous (up to a disconnection event) w.r.t. SLE\(_{\kappa} \)(\( D, z_0, z_n \)); the Loewner chain is \((K_s)\), the trace \( \gamma \), the measure \( \mu_c \). The second one is absolutely continuous (up to a disconnection event) w.r.t. SLE\(_{\kappa} \)(\( D, z_n, z_{n+1} \)); the Loewner chain is \((\hat{K}_t)\), the trace \( \hat{\gamma} \), the measure \( \hat{\mu}_c \). We also denote \( c_{s,t} = (D \setminus (K_s \cup \hat{K}_t), z_0, z_1, \ldots, z_n, \hat{\gamma}_t) \).

From Theorem 4 and the following discussion, we know that \( \hat{\kappa} \in \{\kappa, 16/\kappa\} \) and there is a positive conformally invariant function \( \psi \) on configurations, weights \( \nu_{t,j} \), such that for \( \tau, \hat{\tau} \) a pair of stopping times (before disconnection events)

\[
\ell_c(\gamma^\tau, \hat{\gamma}^\tau) = \left( \frac{Z(c_{\tau,\hat{\tau}})Z(c_0,0)}{Z(c_{\tau,0})Z(c_{0,\hat{\tau}})} \right) \exp(-\lambda m(D; K_\tau, \hat{K}_\hat{\tau}))
= \left( \frac{d\mu_{c,\tau}}{d\mu_{c,0}} \hat{\gamma}^\tau \right) \left( \frac{d\hat{\mu}_{c,0}}{d\hat{\mu}_{c,\tau}} \right) \hat{\gamma}^\tau
\]

where \( Z(c) = \psi(c) \prod_{i<j} H_D(z_i, z_j)^{\nu_{ij}} \).

Let \( \hat{\gamma}^\tau \) be a fixed stopped path. Let \( \tau \) be a stopping time for \( \gamma \) conditional on \( \hat{\gamma}^\tau \), such that a.s. \( \gamma^\tau \) is at distance at least \( \eta > 0 \) of \( \hat{\gamma}^\tau \) and other marked points. Then we deduce immediately from (4.6) that:

\[
\int \ell_c(\gamma^\tau, \hat{\gamma}^\tau) d\mu_{c,\tau}(\gamma^\tau) = \int d\hat{\mu}_{c,\tau}(\gamma^\tau) = 1 \quad \forall \hat{\gamma}^\tau
\]

The symmetric statement holds for the same reason.

Define:

\[
\ell_{s_1, t_1}^{s_2, t_2} = \ell_{c_{s_1, t_1}}(\gamma_{s_2, t_2}) = \left( \frac{Z(c_{s_2, t_2})Z(c_{s_1, t_1})}{Z(c_{s_2, t_1})Z(c_{s_1, t_2})} \right) \exp(-\lambda m(D \setminus (K_{s_1} \cup \hat{K}_{t_1}); K_{s_2}, \hat{K}_{t_2})).
\]

We recall the (deterministic) tower property: for \( 0 \leq s_1 \leq s_2 \leq s_3, 0 \leq t_1 \leq t_2 \leq t_3 \) such that \( c_{s_3, t_3} \) is a configuration

\[
\ell_{s_1, t_1}^{s_2, t_2} \ell_{s_3, t_3}^{s_2, t_2} = \ell_{s_1, t_1}^{s_3, t_3}, \quad \ell_{s_1, t_1}^{s_2, t_2} \ell_{s_2, t_2}^{s_3, t_3} = \ell_{s_1, t_1}^{s_3, t_3}.
\]

The goal of this section is to use these properties to extend a local coupling of \( \mu_c, \hat{\mu}_c \), that exists from local commutation, to a maximal coupling “up to disconnection.” The idea, introduced in [16] in the case of reversibility, is to consider a sequence of couplings absolutely continuous w.r.t. the independent coupling \( \mu_c \otimes \hat{\mu}_c \) that converges to a maximal coupling. The construction of the coupling presented here somewhat differs from that in [16]. The existence of a such a maximal coupling relies solely on (4.7), (4.8), and the SLE Markov property.
4.1 Local coupling

We briefly discuss here the interpretation of local commutation [116] in terms of couplings.

A coupling of $\mu_c, \hat{\mu}_c$ is a measure on pairs of paths $(\gamma, \hat{\gamma})$ (or chains $(K, \hat{K})$) such that the first marginal is $\mu_c$, the second marginal is $\hat{\mu}_c$. The trivial (independent) coupling is $\mu_c \otimes \hat{\mu}_c$.

For simplicity, consider $U, \hat{U}$ disjoint neighbourhoods of $x, y$ respectively in $D$ at positive distance of other marked points. Let $\tau, \hat{\tau}$ be the first exit of $U, \hat{U}$ by $\gamma, \hat{\gamma}$. Then we can consider the measure on pairs of stopped paths $(\gamma^\tau, \hat{\gamma}^{\hat{\tau}})$ given by:

$$\ell_c(\gamma^\tau, \hat{\gamma}^{\hat{\tau}})d\mu_c(\gamma^\tau)d\hat{\mu}_c(\hat{\gamma}^{\hat{\tau}})$$

From (4.7), we know that this is a coupling of the stopped measures $\mu_c^\tau, \hat{\mu}_c^{\hat{\tau}}$. One can extend it to a coupling of $\mu_c, \hat{\mu}_c$ as follows: after $\tau, \gamma$ is continued as an SLE in $c_{\tau,0}$ (that is, following $\mu_{c_{\tau,0}}$) independent of the rest conditionally on $c_{\tau,0}$; $\hat{\gamma}$ is continued in a similar way. This describes a coupling of $\mu_c, \hat{\mu}_c$, using the (strong) Markov property. It is clear that this procedure describes the measure:

$$\ell_c(\gamma^\tau, \hat{\gamma}^{\hat{\tau}})d\mu_c(\gamma^\tau)d\hat{\mu}_c(\hat{\gamma})$$

on pairs of paths $(\gamma, \hat{\gamma})$. This coupling is local in the sense that the interaction is restricted to the time set $[0, \tau] \times [0, \hat{\tau}]$. In the next subsection, we will extend the interaction to the (random) time set $\{(s, t) : K_s \cap K_t = \emptyset\}$.

4.2 Maximal coupling

The goal here is to construct explicit couplings of $\mu_c, \hat{\mu}_c$ parameterized by a small parameter $\eta > 0$ such that any subsequential limit as $\eta \downarrow 0$ is a maximal coupling.

We assume $\eta \ll \text{dist}(z_0, z_{n+1}) \leq \text{diam}(D) < \infty$. (The domain $D$ is embedded in the plane and distances are measured in the ambient plane).

Define by induction the stopping times: $\tau_0 = 0$;

$$\tau_{i+1} = \inf\{t \geq 0 : \gamma_t \notin (K_{\tau_i})^\eta\}$$

where $A^\eta = \{x \in D : \text{dist}(x, A) < \eta\}$. Then $\tau_i$ is a function of the path $\gamma$ (taking a modification where traces exist and are continuous). The sequence $\tau_i$ is strictly increasing until it reaches $\infty$.

If $\tau_n < \infty$, then for all $i < j \leq n$, $\text{dist}(\gamma_{\tau_i}, \gamma_{\tau_j}) \geq \eta$, since $\gamma_{\tau_i}$ is outside of $(K_{\tau_{i-1}})^\eta$. Thus $n\pi(\frac{2}{\eta})^2 \leq \text{area}(D + B(0, \eta))$. This gives a fixed $N = \lceil 4\text{area}(D + B(0, \eta))/\pi \rceil$ such that $\tau_N = \infty$.

Similarly, define $\hat{\tau} = 0$, and by induction:

$$\hat{\tau}_{j+1} = \inf\{t \geq 0 : \hat{\gamma}_t \notin (\hat{K}_{\hat{\tau}_i})^\eta\}.$$  

We now introduce a dependence on the other path. Let $\partial$ be the smallest connected boundary arc of $D$ containing all marked points except $z_0$; symmetrically, $\hat{\partial}$ be the smallest connected boundary arc of $D$ containing all marked points except $z_{n+1}$. These two arcs overlap in general.

We define a (random) set $G \subset \mathbb{N}^2$ of good pairs of indices as follows:

$$\{(i, j) \in G\} = \{\text{dist}(K_{\tau_i}, \hat{K}_{\hat{\tau}_j}) > 3\eta\} \cap \{\text{dist}(K_{\tau_i}, \partial) > 2\eta\} \cap \{\text{dist}(\hat{K}_{\hat{\tau}_j}, \hat{\partial}) > 2\eta\}.$$  

(Here, $\text{dist}(K, \hat{K}) = \inf_{x \in K, \hat{x} \in \hat{K}} \text{dist}(x, \hat{x})$). This is a separation condition. If $i' \leq i, j' \leq j$, $(i, j) \in G$, then a fortiori $i', j' \in G$. We take $\eta$ small enough so that $(0, 0) \in G$.

For conciseness, denote

$$\ell_{ij}^{i',j'} = \ell_{\tau_i, \hat{\tau}_j}^{\tau_{i'},\hat{\tau}_{j'}} = \ell_{c_{\tau_i, \hat{\tau}_j}}(\gamma^{\tau_i, \hat{\tau}_j}, \hat{\gamma}^{\tau_{i'}, \hat{\tau}_{j'}})$$

8
for \( i \leq i', j \leq j' \). If \( \tau_i = \tau_{i'} \), set \( \ell_{i,j}^{i',j'} = 1 \) (this is the case if \( i = i' \) or \( \tau_i = \tau_{i'} = \infty \)).

Let \((i, j) \in G\). Then \( K_{\tau_i} \) is at distance at least \( 3\eta \) from \( K_{\tau_j} \) and at least \( 2\eta \) from \( \partial \). Thus \( K_{\tau_{i+1}} \subset (K_{\tau_i})^\eta \) is at distance at least \( 2\eta \) from \( K_{\tau_{i+1}} \), at least \( \eta \) from \( K_{\tau_{i+1}} \), and at least \( \eta \) from \( \partial \). Symmetric statements hold for \( K_{\tau_j} \). Thus \( \ell_{i,j}^{i+1,j+1} \) is well defined and by Lemma 14 uniformly bounded by some \( C = C(D, \eta) \).

Define

\[
I(j) = \inf \{ i \in \mathbb{N} : (i, j) \notin G \}
\]

\[
J(i) = \inf \{ j \in \mathbb{N} : (i, j) \notin G \}.
\]

Plainly, \( I \) and \( J \) are nonincreasing. If \( \mathcal{F} \) (resp. \( \hat{\mathcal{F}} \)) is the filtration generated by \( \gamma \) (resp. \( \hat{\gamma} \)), \( \tau_i \) is an \( \mathcal{F} \)-stopping time. Also, the event \( \{(i, j) \in G\} \) is \( (\mathcal{F}_{\tau_i} \lor \hat{\mathcal{F}}_{\hat{\tau}_j}) \)-measurable. It follows that \( \tau_{I(j)} \) is a stopping time in the enlarged filtration \( (\mathcal{F}_i \lor \hat{\mathcal{F}}_{\hat{\tau}_j})_t \). Symmetric statements hold for \( \hat{\tau}_j, \hat{\tau}_{J(i)} \).

Consider the measure \( \Theta^\gamma_c \) on pairs \((\gamma, \hat{\gamma})\):

\[
d\Theta^\gamma_c(\gamma, \hat{\gamma}) = \prod_{(i, j) \in G} \ell_{i,j}^{i+1,j+1} d\mu_c(\gamma) d\hat{\mu}_c(\hat{\gamma})
\]

The density is a function on pairs \((\gamma, \hat{\gamma})\). From the tower property (5.3), one can rewrite this density as:

\[
L = \prod_{(i, j) \in G} \ell_{i,j}^{i+1,j+1} = \prod_{0 \leq i \leq N} \ell_{i,0}^{i+1,J(i)} = \prod_{0 \leq j \leq N} \ell_{0,j}^{J(j)+1}
\]

showing in particular that \( L \) is bounded by \( C^N \). The last two expressions of \( L \) will behave well in combination with the Markov property of \( \gamma, \hat{\gamma} \) respectively.

**Lemma 5.** The measure \( \Theta^\gamma_c = L(\mu_c \otimes \hat{\mu}_c) \) is a coupling of \( \mu_c, \hat{\mu}_c \).

**Proof.** The statement can be rephrased as

\[
\forall \hat{\gamma}, \mathbb{E}(L) = 1 \quad \forall \gamma, \hat{\mathbb{E}}(L) = 1
\]

where \( \mathbb{E}, \hat{\mathbb{E}} \) refer to integration w.r.t. \( d\mu_c(\gamma), d\hat{\mu}_c(\hat{\gamma}) \) respectively (in other terms \( \mathbb{E}(.) = \mathbb{E} \otimes \hat{\mathbb{E}}(|\hat{\mathcal{F}}_\infty|) \)). The situation is completely symmetric, so we shall consider only the distribution of the second marginal; that is, we have to check that given any \( \hat{\gamma}, \mathbb{E}(L) = 1 \).

For this, the relevant expression of the density is: \( L = \prod_{0 \leq i \leq N} \ell_{i,0}^{i+1,J(i)} \). Notice that \( \hat{\gamma}_{J(i)} \) is \( \mathcal{F}_{\tau_i} \lor \hat{\mathcal{F}}_\infty \)-measurable. This implies that a term \( \ell_{i,0}^{i+1,J(i)} \) is \( \mathcal{F}_{\tau_n} \lor \hat{\mathcal{F}}_\infty \)-measurable for any \( i < n \). Thus for fixed \( n \):

\[
\mathbb{E} \left( \prod_{i=0}^n \ell_{i,0}^{i+1,J(i)} | \mathcal{F}_{\tau_n} \right) = \prod_{i=0}^{n-1} \mathbb{E}(\ell_{i,0}^{i+1,J(i)} | \mathcal{F}_{\tau_n})
\]

and \( \mathbb{E}(\ell_{0,0}^{n+1,J(n)} | \mathcal{F}_{\tau_n}) = 1 \) by (5.4); the point is that given \( \mathcal{F}_{\tau_n} \lor \hat{\mathcal{F}}_\infty \), \( \gamma^\tau_n \) and \( \hat{\gamma}_{J(n)} \) are fixed. This is saying that

\[
M_n = \prod_{i=0}^{n-1} \ell_{i,0}^{i+1,J(i)}
\]

is a (discrete time, bounded) martingale in the filtration \( \mathcal{F}_{\tau_n} \lor \hat{\mathcal{F}}_\infty \). In particular, \( \mathbb{E}(L) = \mathbb{E}(M_N) = M_0 = 1 \). \( \square \)
We can actually get a more precise statement. Let $\tau$ be an arbitrary $\mathcal{F}$-stopping time; let $n = \inf \{ i \in \mathbb{N} : \tau_i \geq \tau \}$, a random integer. We assume that $\text{dist}(\gamma^n, \partial) \geq 3\eta$ a.s., so that $(n,0) \in \mathcal{G}$. Then $\tau_n$ is a stopping time approximating $\tau$ (as $\eta \searrow 0$). Consider the joint distribution of $(\gamma^n, \hat{\tau}_{\mathcal{F}(n)})$ under $\Theta^n$. Then $\gamma^n$ has distribution $\mu^{\tau_n}_c$. Moreover:

$$
\mathbb{E} \otimes \hat{\mathbb{E}} \left( L | \mathcal{F}_{\tau_n} \vee \hat{\mathcal{F}}_{\mathcal{F}(n)} \right) = \prod_{i \geq n} \ell_{i,0}^{i+1,J(i)}(0) \mathbb{E} \otimes \hat{\mathbb{E}} \left( \prod_{i \geq n} \ell_{i,0}^{i+1,J(i)}(0) \prod_{j \geq J(n)} \ell_{0,j}^{I(j),j+1}(0) | \mathcal{F}_{\tau_n} \vee \hat{\mathcal{F}}_{\mathcal{F}(n)} \right)
$$

The term $\prod_{i \geq n} \ell_{i,0}^{i+1,J(i)}(0)$ involves $\gamma$ after $\tau_n$ and $\hat{\gamma}$ before $\hat{\tau}_{\mathcal{F}(n)}$ (if $i \geq n$, $J(i) \leq J(n)$); the other term, $\prod_{j \geq J(n)} \ell_{0,j}^{I(j),j+1}(0)$, involves $\gamma$ after $\tau_n$ and $\hat{\gamma}$ before $\tau_n$. Hence these two terms are independent conditionally on $(\mathcal{F}_{\tau_n} \vee \hat{\mathcal{F}}_{\mathcal{F}(n)})$ (under the independent measure $\mu_c \otimes \hat{\mu}_c$). Moreover

$$
\mathbb{E}(\ell_{i,0}^{i+1,J(i)} | \mathcal{F}_{\tau_n}) = \mathbb{E}\left( \frac{M}{M_n} | \mathcal{F}_{\tau_n} \right) = 1
$$

where $(M_N)$ is the discrete-time, bounded martingale considered in the previous lemma, since $n$ is a stopping time for its discrete filtration. Similarly, $\hat{\mathbb{E}}(\ell_{i,0}^{i+1,J(i)} | \hat{\mathcal{F}}_{\mathcal{F}(n)}) = 1$, and consequently:

$$
\mathbb{E} \otimes \hat{\mathbb{E}} \left( L | \mathcal{F}_{\tau_n} \vee \hat{\mathcal{F}}_{\mathcal{F}(n)} \right) = \left( \mathbb{E} \otimes \hat{\mathbb{E}} \left( \prod_{i \geq n} \ell_{i,0}^{i+1,J(i)}(0) | \mathcal{F}_{\tau_n} \right) \right) \left( \mathbb{E} \otimes \hat{\mathbb{E}} \left( \prod_{j \geq J(n)} \ell_{0,j}^{I(j),j+1}(0) | \mathcal{F}_{\tau_n} \vee \hat{\mathcal{F}}_{\mathcal{F}(n)} \right) \right)
$$

This proves that under $\Theta^n$, the conditional distribution of $\hat{\tau}_{\mathcal{F}(n)}$ given $\gamma^n$ is $\mu^{\tau_n}_{\mathcal{F}(n)}$, where $\hat{\tau}_{\mathcal{F}(n)}$ is a stopping time conditionally on $\gamma^n$.

To phrase the following theorem, it is convenient to introduce:

$$
\sigma = \sup \{ t \geq 0 : K_t \cap \partial = \emptyset \}
$$

$$
\hat{\sigma} = \sup \{ t \geq 0 : \hat{K}_t \cap \partial = \emptyset \}
$$

The measures $\mu_c$, $\hat{\mu}_c$ are defined on paths $(\gamma, \hat{\gamma})$ up to $\sigma, \hat{\sigma}$.

**Theorem 6.** Let $\mu_c, \hat{\mu}_c$ be SLE measures in a configuration $(D, z_0, \ldots, z_{n+1})$ satisfying local commutation. Then there exists a coupling $\Theta$ of $\mu_c$, $\hat{\mu}_c$ which is maximal in the following sense:

for any $\mathcal{F}$-stopping time $\tau$, $\tau \leq \sigma$, let $\hat{\tau}$ be the $(\mathcal{F}_\tau \vee \hat{\mathcal{F}}_t)$-stopping time:

$$
\hat{\tau} = \sup \{ t \geq 0 : \hat{K}_t \cap (K_\tau \cup \partial) = \emptyset \}
$$

Then under $\Theta$, the pair $(\gamma, \hat{\gamma})$ has the following distribution: $\gamma$ is distributed according to $\mu^\tau_c$, and conditionally on $\gamma$, $\hat{\gamma}$ is distributed according to $\hat{\mu}^\tau_c$. The symmetric statement holds.
Proof. For any $\eta > 0$, the two marginal distributions of $\Theta^\eta$ are fixed Radon measures (in the topology of Carathéodory convergence of Loewner chains). Thus the family $(\Theta^\eta)_{\eta > 0}$ is tight, and Prokhorov’s theorem ensures existence of subsequential limits. Let $(\eta_k)_k$ be a sequence $\eta_k \to 0$ along which $\Theta^{\eta_k}$ has a weak limit $\Theta$. Then $\Theta$ is a coupling of $\mu_c$ and $\mu_{\xi}$. We can consider a probability space with sample $((\gamma^1, \tilde{\gamma}^1), \ldots, (\gamma^k, \tilde{\gamma}^k), \ldots)$ such that the distribution of $(\gamma^k, \tilde{\gamma}^k)$ is $\Theta^{\eta_k}$ and $(\gamma^k, \tilde{\gamma}^k) \to (\gamma, \tilde{\gamma})$ a.s., where the distribution of $(\gamma, \tilde{\gamma})$ is $\Theta$.

Let $\tau$ be an $F$-stopping time; we approximate $\tau$ in a convenient way. Firstly, $\tau$ can be approximated by $\tau'$ taking values in some discrete countable sequence $(t_i)_{i \geq 0}$ (eg dyadic times). Hence there are Borel sets $B_i$ such that $1_{B_i}$ is a Borel function of $K^t_i$ and $\tau' = \inf\{t_i : K_{t_i} \in B_i\}$. Replace the Borel set $B_i$ by a larger open set $U_i$ such that the measure of $U_i \setminus B_i$ is very small. Then $\tau'' = \inf\{t_i : K_{t_i} \in U_i\}$ is a stopping time equal to $\tau'$ with probability arbitrarily close to 1. Finally, let $\tau''' = \tau'' \wedge \sup\{t : \text{dist}(\gamma_t, \partial) \geq \varepsilon'\}$ for some fixed $\varepsilon' > 0$. Let us assume for now that $\tau$ is of type $\tau'''$. This gives a common stopping rule for all the chains $K^k$: stop the first time that $K^k_{\tau_k}$ is in $U_i$ or at distance $\varepsilon$ of $\partial$. We denote $\tau^k$ this stopping time for the chain $K^k$. In particular, $\tau^k \to \tau$ a.s. (using that the $U_i$’s are open).

For $\eta > 0$, $\tau^k_n$ is an approximation of $\tau^k$ as above: $\tau^k_n = \inf\{t_i : \tau^k_i \geq \tau^k\}$; then

$$K^k_{\tau^k_n - 1} \subset K^k_{\tau^k_n} \subset K^k_{\tau^k_n + 1} = (K^k_{\tau^k_n})^{\eta_k}.$$  

It is easy to see that $\tau^k_n \to \tau$, $\tau_{n-1}^k \to \tau$, $K^k_{\tau^k_n} \to K^\tau$ and $\gamma^k_{\tau^k_n} \to \gamma_\tau$ (since $\gamma_\tau = \cap_{n>0} K_{\tau^k_n} \setminus K^\tau$) as $k \to \infty$. We have seen that the conditional distribution of $\gamma_{\tau^k(n)}$ is $\mu_{c_{\tau^k(n)}}$. Notice that $\gamma_{\tau^k(n)}$ occurs after first entrance in $(K^k_{\tau^k_n})^{3\eta_k}$ and before entrance in $(K^k_{\tau^k_n})^{\eta_k}$.

For fixed $\varepsilon > 0$, $K^k_{\tau^k_n} \subset (K^\tau)^\varepsilon$ for $k$ large enough. The configuration $\gamma^{k_{\tau^k(n)}}_{\tau^k(n)}$ converges in the Carathéodory topology to $c_{\tau,0}$ (with also convergence of $\gamma^k_{\tau^k_n}$ to $\gamma_\tau$): this implies weak convergence of the conditional distribution of $\gamma_{\tau^k}$ stopped when entering $(K^k)^\varepsilon$ to the corresponding stopped SLE in $c_{\tau,0}$. This gives the correct conditional distribution of $\gamma$ stopped when entering $(K^\tau)^\varepsilon$, conditional on $\gamma^\tau$. One concludes by taking $\varepsilon \to 0$.

This proves the result for a dense set of stopping times of type $\tau'''$ as above (this will be enough to draw geometric consequences). A general stopping time $\tau \leq \sigma$ is the limit of a sequence of stopping times $\tau^{\prime\prime\prime}_m$, for each $m$, the conditional distribution of $\gamma$ stopped upon entering $(K^\tau)^\varepsilon$ is correct. One concludes by taking $m \to \infty$ and then $\varepsilon \to 0$.  

There are some obvious extensions of this result. One involves radial SLE’s (not necessarily aiming at the same bulk point). Another involves systems of $n$ (pairwise) commuting SLE’s. Let us discuss this case briefly.

Consider a configuration $c = (D, z_1, \ldots, z_n, z_{n+1}, \ldots, z_{n+m})$, with $n$ SLE’s starting at $z_1, \ldots, z_n$, driven by the same partition function $Z$. One can reason as above (sampling the SLE’s at discrete times $\tau_{i_1}, \ldots, \tau_{i_n}$). In a maximal coupling, one can stop the first SLE at a stopping time $\tau^1$, the second at $\tau^2$ (first time it ceases to be defined or meets $K^1_{\tau^1}$), $\ldots$, the $n$-th at $\tau^n$ (first time it ceases to be defined or meets $\cup_{i=1}^{n-1} K^i_{\tau^i}$) and get the appropriate joint distribution. This works for any permutation of indices.

Let us describe the local coupling in this case: let $U_1, \ldots, U_n$ be disjoint neighbourhoods of $z_1, \ldots, z_n$, $\mu^1, \ldots, \mu^n$ the commuting SLE measures, $Z$ their common partition function. Let $K_i$ be the hull of the stopped $i$-th SLE; $c_{\varepsilon_1, \ldots, \varepsilon_n}, \varepsilon_i \in \{0, 1\}$, is the configuration where the $i$-th SLE has grown (until stopped) if $\varepsilon_i = 1$. Consider the density

$$L = \frac{d\mu^n_{c_{1,1,0,0}}}{d\mu^0_{c_{1,1,0,0}}} \cdot \frac{d\mu^{n-1}_{c_{1,1,0,0}}}{d\mu^0_{c_{1,1,0,0}}} \cdots \frac{d\mu^2_{c_{1,1,0,0}}}{d\mu^0_{c_{1,1,0,0}}} = Z(c_{1,1,0,0}) Z(c_{0,0,0,0})^{n-1} \exp \left( -\lambda \sum_{j=2}^n m(D, z_{j-1} K_i, K_j) \right).$$

Then it is clear from the first expression that the first marginal of $L(\mu^1_c \otimes \cdots \otimes \mu^n_c)$ is $\mu^1_c$ (integrating out
Determines the parameterized trace. Hence in any maximal coupling \( \Theta \), \( \hat{\gamma} \) determines the coupling uniquely.

\( \gamma \) the boundary only at its endpoints. Hence \( \hat{\gamma} \) is connected. Hence the occupied sets of \( \gamma \), dense in \( \gamma \), counterclockwise order. Let \( z \).

Then we can consider chordal SLE from \( z \).

Assume that \( \tau \).

Let \( \kappa \).

Then the traces of SLE.

Let \( \kappa \).

Zero level line of a discrete free field ([12]) number); denote simply by \( \tau \).

In the maximal coupling \( \Theta \), the conditional distribution of \( \hat{\gamma} \) is SLE in \( D \setminus K_r, y, \gamma_r \) stopped upon hitting \( K_r \). For \( \kappa \leq 4 \), the SLE trace intersects the boundary only at its endpoints. Hence \( \hat{\gamma} = \gamma_r \). This proves that under \( \Theta \), the intersection \( \gamma \cap \hat{\gamma} \) is a.s. dense in \( \gamma \). Since both \( \gamma, \hat{\gamma} \) are a.s. closed, \( \gamma \subset \hat{\gamma} \); since \( \hat{\gamma} \) is simple, removing a point disconnects it, but \( \gamma \) is connected. Hence the occupied sets of \( \gamma, \hat{\gamma} \) are equal. Again, as the paths are simple, the occupied set determines the parameterized trace. Hence in any maximal coupling \( \Theta \), \( \hat{\gamma} = \gamma^r \) (the reverse trace) a.s.; this determines the coupling uniquely.

Besides local commutation, the argument uses only qualitative properties of the paths. So we can phrase at no additional cost:

**Corollary 8.** Let \( \kappa \leq 4 \), \( \mu_c, \hat{\mu}_c \) a system of commuting SLE in the configuration \( c = (D, z_0, z_1, \ldots, z_n, z_{n+1}) \). Assume that \( \mu_c, \hat{\mu}_c \) are supported on simple paths that meet the boundary of \( D \) only at \( z_0, z_{n+1} \). Then \( \gamma^r \) and \( \hat{\gamma} \) are identical in distribution.

A simple example of the situation is as follows: let \( (z_1, \ldots, z_4) \) be four marked points on the arc \( (z_0 z_5) \). Then we can consider chordal SLE from \( z_1 \) to \( z_5 \) weighted by any, say, bounded above and below function of the cross-ratio of \( (z_1, \ldots, z_4) \) in \( D \setminus \gamma \). This plainly preserves both local commutation and reversibility.

Another setup where the corollary applies is the following: \( c = (D, z_0, z_1, \ldots, z_{n+1}) \) with points in counterclockwise order. Let \( \rho_1, \ldots, \rho_n \) be such that \( \rho_1 + \cdots + \rho_i \geq 0 \) for \( 1 \leq i < n \) and \( \rho_1 + \cdots + \rho_n = 0 \). Then the traces of SLE\((\rho, -2)\) starting from \( z_0 \) and SLE\((-2, -\rho)\) starting from \( z_{n+1} \) are the reverse of each other in distribution. This describes the scaling limit of the zero level line of a discrete free field ([12]) with piecewise constant boundary conditions (with jump at \( z_i \) proportional to \( \rho_i \)). A version with marked points on both sides of \( z_0 \) also holds.

One also obtains reversibility identities for the pairs of commuting SLE’s (aiming at each other) with four marked points described at the end of Section 3.2. By degenerating two points into one, this describes the reversal of SLE\(_{\kappa}(\rho)\), \( \kappa \leq 4 \), \( \rho \geq \frac{4}{\kappa} - 2 \). For instance, if \( \kappa = 8/3 \), one can represent an SLE\(_{8/3}(\rho)\) in \((\mathbb{H}, 0, 1, \infty)\) as the limit of a chordal SLE\(_{8/3}\) in \((\mathbb{H}, 0, \infty)\) conditioned not to intersect a restriction measure with exponent \( \nu = \nu(\rho) \) from \( 1 \) to \( z \gg 1 \) ([14]; reversibility in this case follows from [5]). For general \( \kappa \), it
is unclear whether there is a simple probabilistic interpretation, but one still gets an exact (if unwieldy in general) description of the reversal.

**Corollary 9.** Let $\kappa \leq 4$, $\rho \geq \frac{\kappa}{2} - 2$, $(D, x, y)$ a configuration. Then SLE$_{\kappa}(\rho)$ in $(D, x, y, x^+)$ and in $(D, y, x, y^-)$ have the same occupied set in distribution, where $x, x^+, y, y^-$ are in this order on the boundary.

**Proof.** We sketch the argument. The result follows from reversibility in the regular situation with four marked points described at the end of Section 3.2. Indeed, if $x, z_1, z_2, y$ are in this order on the boundary, one has a pair of commuting SLE’s starting at $x, y$ with common partition function: $Z(c) = H_D(x, y)^{\frac{\kappa - 4}{2\kappa}} H_D(z_1, z_2)^\nu \psi(u)$ where $u$ is the cross-ratio $u = \frac{(z_1 - x)(z_2 - y)}{(y - x)(z_2 - z_1)}$ (in the upper half-plane), $\frac{\kappa}{2}(\beta - 1) + 2\beta = 2\nu$ and

$$
\psi(u) = (u(1 - u))^\beta {\text{2F1}(2\beta, 2\beta + \frac{8}{\kappa} - 1; 2\beta + \frac{4}{\kappa}; u)}.
$$

When $\kappa \leq 4$, $\rho = \kappa\beta \geq \frac{\kappa}{2} - 2$, the processes do not hit $[z_1, z_2]$, by comparison arguments. Thus the local commutation extends to a maximal coupling, and in this coupling the occupied sets coincide.

The first SLE is the martingale transform of chordal SLE$_{\kappa}$ in $(D, x, y)$ by the martingale (in upper half-plane coordinates):

$$
t \mapsto \left( \frac{g_1'(z_1)g_1'(z_2)}{(g_1(z_1) - g_1(z_2))^2} \right) \nu \psi(u_t)
$$

where $u_t$ is the cross-ratio at time $t$. Take $z_2 = y - \varepsilon$. Then the leading term of the expansion of the martingale as $\varepsilon \searrow 0$ is:

$$
t \mapsto \left( \frac{g_1'(z_1)g_1'(y)}{(g_1(z_1) - g_1(y))^2} \right) \nu \left( \frac{(g_1(z_1) - X_1)g_1'(y)}{(g_1(y) - X_1)(g_1(y) - g_1(z_1))} \right)^\beta
$$

so that this limiting process is identified from Lemma 12 as SLE$_{\kappa}(\rho)$ in $(D, x, y, z_1)$, $\rho = \kappa\beta$. A symmetric result holds for the other SLE.

The same arguments can be used to establish reversibility of systems of multiple SLE’s considered in [2] (this also follows from the symmetry of the density of the system w.r.t. independent chordal SLE’s when the pairing of endpoints is fixed).

### 5.2 Duality

The question of SLE duality is to describe boundaries of SLE$_{\kappa}$, $\kappa > 4$, in terms of SLE$_{\tilde{\kappa}}$, $\tilde{\kappa} = 16/\kappa$.

There are various parametric situations we can consider. Let us start with the simplest setting: a configuration $c = D(x, z_1, y, z_2)$ has four marked points $x, y, z_1, z_2$ on the boundary. We consider two SLE’s (inducing the measures $\mu_c, \hat{\mu}_c$, with traces $\gamma, \hat{\gamma}$), see Table 1 ($[\kappa]$ represents an SLE$_{\kappa}$ “seed”, the other entries are the $\rho$ parameters).

| $x$ | $z_1$ | $y$ | $z_2$ |
|-----|-------|-----|-------|
| $\kappa$ | $\rho_1$ | $\frac{\kappa}{2}$ | $\rho_2$ |
| $\frac{\kappa}{2}$ | $\rho_1$ | $[\kappa]$ | $\rho_2$ |

The additional conditions for local commutation are $\rho_1 + \rho_2 = \frac{3}{2}(\kappa - 4)$, $\hat{\rho}_1 = -\frac{4}{\kappa}\rho_1$, consequently $\hat{\rho}_1 + \hat{\rho}_2 = \frac{3}{2}(\hat{\kappa} - 4)$. This leaves one free parameter, say $\rho_1 = \rho$. We need to put conditions on $\rho$ so that
paths have a correct geometry. Take \( \rho \in [\frac{\kappa - 4}{2}, \kappa - 4] \), a nonempty interval when \( \kappa > 4 \). Consequently, \( \rho_2 \in [\frac{\kappa - 4}{2}, \kappa - 4] \), \( \hat{\rho}_1, \hat{\rho}_2 \in [\frac{\kappa - 4}{2}, \kappa - 4] \). Then the first SLE will first intersect \([z_1, z_2]\) at \( y \) (see Lemma 13). To restrict even more the situation, take \( \hat{\rho}_1 = \kappa - 4 \) (or symmetrically \( \hat{\rho}_2 = \kappa - 4 \)). Then the second SLE cannot hit \((z_2, x)\), nor \((z_1, z_2)\) except at \( y \); and it hits \((x, z_1)\) since \( \hat{\rho}_1 = \kappa - 4 < \frac{\kappa}{2} - 2 \).

**Proposition 10.** In a maximal coupling \( \Theta \) of \( \mu_c, \hat{\mu}_c \), the range of \( \hat{\gamma} \) is contained in that of \( \gamma \). If \( \rho_1 = \kappa - 4 \), \( \hat{\gamma} \) is the right boundary of \( K \); if \( \rho_2 = \kappa - 4 \), \( \hat{\gamma} \) is the left boundary of \( K \).

**Proof.** As before, take \( \hat{\tau} \) a stopping time for the second SLE. The first SLE in \( c_0, \hat{\tau} \) is defined until it exits at \( \hat{\gamma}_\tau \). More precisely, it is defined up to a time where it accumulates at \( \hat{\gamma}_\tau \) and at no other point of the boundary arc \([z_1, z_2]\) of \( c_0, \hat{\tau} \) (Lemma 15). But \( \gamma \) is continuous away from \([z_1, z_2]\) in \( c_0 \); so if \( \hat{\tau} \) is positive, \( \gamma \) stopped when exiting \( c_0, \hat{\tau} \) has a limit, which is \( \hat{\gamma}_\tau \). Hence \( \hat{\gamma}_\tau \) is on \( \gamma \). Taking countably many stopping times, this shows that \( \hat{\gamma} \) is included in (the range of) \( \gamma \). Moreover, ordering is preserved: \( \hat{\gamma}_\tau = \gamma_t \) for some \( t \leq \tau \), and for any \( t < \hat{\tau}, \hat{\gamma}_t \notin K_\tau \).

Set \( \rho_1 = \kappa - 4 \). Then the range of \( \gamma \) is partitioned in points on \( \hat{\gamma} \), to its left, or to its right. Take a stopping time \( \tau \). Then \( \hat{\gamma} \) first hits \( K_\tau \) on the arc \([\gamma_\tau, z_1]\). If \( \gamma_\tau \) was to the right of \( \hat{\gamma} \), then \( \hat{\gamma} \) would have to circle \( \gamma_\tau \) and reenter in \( K_\tau \), which would violate the ordering condition. Hence a generic point \( \gamma_\tau \) is on \( \hat{\gamma} \) or to its left. This implies that \( \hat{\gamma} \) is contained in the right boundary of the range of \( \gamma \), which is a simple path. Since \( \hat{\gamma} \) starts at \( y \) (where \( \gamma \) ends) and ends on \((x, z_1)\), this shows that \( \hat{\gamma} \) is the right boundary of the range of \( \gamma \).

**Remark 11.** The situation where \( \rho \in [\frac{\kappa - 4}{2}, \kappa - 4] \) is of some independent interest and seems related to pivotal points questions.

We consider now versions where the non simple SLE is actually chordal SLE \( \kappa \), at the expense of some complication for the dual simple SLE \( \hat{\kappa} \).

**Proof of Theorem 7** Assume that \( \kappa \in (4, 8) \). Consider chordal SLE \( \kappa \), say in \((\mathbb{H}, 0, \infty)\). The point 1 is swallowed at time \( \tau_1 \); \( D = \gamma_{\tau_1} \) is on \((1, \infty)\) with distribution given by:

\[
P(D \in (1, z)) = F(z) = c \int_{1}^{z} u^{-\frac{\kappa}{2}}(u - 1)\frac{4}{2(\kappa - 2)}du
\]

where \( c = B(1 - 4/\kappa, 8/\kappa - 1)^{-1} \). In other words, \( D^{-1} \) has a Beta\((1 - 4/\kappa, 8/\kappa - 1)^{-1} \) distribution. The function \( F \) is such that \( t \mapsto F((g_t(z) - W_t)/(g_t(1) - W_t)) \) is a martingale. Let us disintegrate the SLE measure w.r.t. \( D \) (see \( \mathbb{H} \) for related questions). It is easy to see that up to \( \tau_1 \), the SLE conditional on \( D = dz \) is the martingale transform of chordal SLE by:

\[
t \mapsto \partial_z F \left( \frac{g_t(z) - W_t}{g_t(1) - W_t} \right) = c \frac{g_t'(z)}{g_t(1) - W_t}(g_t(z) - W_t)^{-\frac{\kappa}{2}}(g_t(z) - g_t(1))^2^{-2}(g_t(1) - W_t)^{-\frac{\kappa}{2}}
\]

and this is readily identified with SLE\( \kappa \) \((\kappa - 4, -4) \) in \((\mathbb{H}, 0, \infty, 1, z)\) (Lemma 12). To get a regular situation, we split the point \( z \) into two points \( y \) and \( z_2 \), while setting \( x = 0 \), \( z_1 = 1 \), \( z_3 = \infty \). Consider the system of commuting SLE’s given by Table 2.

| \( \kappa \) | \( \kappa - 4 \) | \( \frac{\kappa}{2} - 4 \) | \( \frac{\kappa}{2} - 2 \) | \( \frac{\kappa}{2} \) |
|---|---|---|---|---|
| \( \kappa \) | \( \frac{\kappa}{2} - 4 \) | \( \frac{\kappa}{2} - 4 \) | \( \frac{\kappa}{2} - 2 \) | \( \frac{\kappa}{2} \) |
The first SLE hits $[z_1, z_3]$ at $y$, while the second SLE will not hit $[z_2, z_3]$ and exits $[x, z_1]$ somewhere in $(x, z_1)$ (Lemma 15). Arguing as in Proposition 10 this shows that $\hat{\gamma}$ is the right boundary of $K$. Finally, one takes $z_2 \searrow y$, so that the first SLE becomes chordal SLE conditional on $D = y$. This yields Theorem 1.

When $\kappa \geq 8$, the trace is a.s. space filling, and we have to proceed differently to isolate a boundary arc.

Proof of Theorem 2. Consider now the case of a chordal SLE in $(\mathbb{H}, 0, \infty)$, $\kappa \geq 8$ (thus $\hat{\kappa} \leq 2$). Then $\gamma_{\tau_1} = 1$ a.s. There is a leftmost point $G$ on $(\infty, 0)$ visited by the trace before $\tau_1$. We are interested in the boundary of $K_{\tau_1}$, a simple curve from $G$ to some point in $(0, 1)$. Then the distribution of $G$ is given by:

$$P(G \in (z, 0)) = c \int_0^z (-u)^{-4/\kappa} (1 - u)^{-2} \, du$$

where $c = B(1 - 4/\kappa, 1 - 4/\kappa)$ In other words, $G$ is such that $G/(G - 1)$ has a Beta$(1 - 4/\kappa, 1 - 4/\kappa)$ distribution (generalised arcsine distribution). The disintegrated SLE measure w.r.t. $G$ is again SLE$(-4, \kappa - 4)$ in $(\mathbb{H}, 0, \infty, G, 1)$, up to hitting $G$. To get a regular situation, we need to split the point $G$ into three points $z_1, y, z_2$; we also set $x = 0$, $z_3 = 1$, $z_4 = \infty$. Consider the system of two commuting SLE’s in $(\mathbb{H}, y, z_1, x, z_2, z_3)$ given by Table 3.

| $z_1$ | $y$ | $z_2$ | $x$ | $z_3$ | $z_4$ |
|-------|-----|-------|-----|-------|-------|
| $-\frac{2}{\kappa}$ | $\frac{2}{\kappa} - 2$ | $\frac{2}{\kappa} - 2$ | $\kappa - 4$ | $2$ |

The first SLE exits at $y$, the second one exits in $(x, z_3)$ (Lemma 15). As in Proposition 10 this shows that one can couple the two SLE’s such that the second one is the boundary arc of the first one between $y$ and a point of $(x, z_3)$. Taking $z_1 \searrow y$, $z_2 \searrow y$ gives Theorem 2.

At the expense of some complications, one can consider more symmetric situations. Let $(D, x, y, z, z', y', x')$ be a configurations (points are in that order). There is a system of four commuting SLE’s attached to this configuration (where $a + b = 2$), see Table 4.

| $x$ | $y$ | $z$ | $z'$ | $y'$ | $x'$ |
|-----|-----|-----|------|------|------|
| $|\kappa|$ | $a(\kappa - 4)$ | $-\frac{2}{\kappa}$ | $-\frac{2}{\kappa}$ | $b(\kappa - 4)$ | $2$ |
| $\frac{2}{\kappa}$ | $a(\kappa - 4)$ | $-\frac{2}{\kappa}$ | $-\frac{2}{\kappa}$ | $b(\kappa - 4)$ | $|\kappa|$ |
| $-\frac{2}{\kappa}$ | $a(\kappa - 4)$ | $|\kappa|$ | $2$ | $b(\kappa - 4)$ | $-\frac{2}{\kappa}$ |
| $-\frac{2}{\kappa}$ | $a(\kappa - 4)$ | $2$ | $|\kappa|$ | $b(\kappa - 4)$ | $-\frac{2}{\kappa}$ |

6 Some technical results

6.1 Absolute continuity for variants of SLE

In this subsection, we phrase similar absolute continuity results for different versions of SLE. In the context of duality, it is useful to consider SLE-type measures in a parametric family SLE$\kappa(\rho)$ (5 [1]), as acknowledged
An SLE\(_{\kappa}(\rho)\), \(\rho = \rho_1, \ldots, \rho_n\), in the configuration \((\mathbb{H}, x, \infty, z_1, \ldots, z_n)\) is an SLE the driving process of which satisfies the SDE:

\[
dW_t = \sqrt{\kappa}dB_t + \sum_{i=1}^{n} \frac{\rho_i}{W_t - g_t(z_i)} dt
\]

and \(W_0 = x\), up to swallowing of a \(z_i\). See Lemma 3.2 of \[3\] for homographic change of coordinates. In particular, if \(\sum_i \rho_i = \kappa - 6\), the point at infinity is used for normalization only.

The following lemma is a change of measure result (see also \[14\]).

**Lemma 12.** Consider an SLE\(_{\kappa}\) starting from \(x\) in \(\mathbb{H}\), \(\rho = \rho_1, \ldots, \rho_n\); let \(Z_i^\prime = g_t(z_i) - W_t\). Then:

\[
M_t = \prod_i g\prime_t(z_i)^{\alpha_i} |Z_i^\prime|^{\beta_i} \prod_{i<j} |Z_i^\prime - Z_j^\prime|^{\eta_{ij}}
\]

is a local martingale if \(2\alpha_i = \frac{\kappa}{2} \beta_i (\beta_i - 1) + 2 \beta_i, 2\eta_{ij} = \kappa \beta_i \beta_j\). Before the swallowing of any marked point, \(M_t/M_0\) is the density of an SLE\(_{\kappa}(\rho)\) starting from \((x, z_1, \ldots, z_n)\) w.r.t. SLE\(_{\kappa}\), where \(\rho = \kappa \beta_1, \ldots, \kappa \beta_n\).

**Proof.** This is a standard computation relying on:

\[
dZ_i^\prime = \frac{2}{Z_i^\prime} dt - \sqrt{\kappa}dB_t
\]

\[
dg\prime_t(z_i) = - \frac{2}{(Z_i^\prime)^2} dt
\]

so that:

\[
\frac{dM_t}{M_t} = \sum_i \frac{\beta_i}{Z_i^\prime} \left( \frac{2}{Z_i^\prime} dt - \sqrt{\kappa}dB_t \right) - \frac{\kappa}{2} \frac{\beta_i (\beta_i - 1)}{(Z_i^\prime)^2} dt + \sum_{i<j} (\kappa \beta_i \beta_j - 2 \eta_{ij}) \frac{dt}{Z_i^\prime Z_j^\prime}
\]

The statement on the density follows from the Girsanov theorem (e.g. \[10\]), observing that:

\[
\frac{d\langle M_t, W_t \rangle}{M_t} = - \sum \frac{\kappa \beta_i}{Z_i^\prime} dt
\]

that is, the drift term of an SLE\(_{\kappa}(\rho)\) with \(\rho_i = \kappa \beta_i\). More precisely, under the original measure, \(W = \sqrt{\kappa}B\), \(B\) a standard Brownian motion. Under the transformed measure (via the local martingale \(M_t\) stopped away from swallowing a \(z_i\)), \(W = W - \langle W, M \rangle/M\) is a (local) martingale with the same quadratic variation as \(W\); ie, from Lévy’s theorem, a Brownian motion \(\sqrt{\kappa}B\). Hence \(W = \sqrt{\kappa}B + \langle W, M \rangle/M\). \(\square\)

Let \(c = (D, z_0, \ldots, z_n)\) be a configuration. As in Theorem\[4\] we consider a variant of SLE of the following type: let \(\psi\) be a positive, continuous, conformally invariant function on the configuration space and exponents \(\nu_{ij}\) such that if

\[
Z(c) = \psi(c) \prod_{0 \leq i < j \leq n+1} H_D(z_i, z_j)^{\nu_{ij}}
\]

then \(\sum_{j=1}^{n+1} \nu_{0,j} = \alpha_\kappa\) and

\[
M_s = H_D(z_0, z)^{\alpha_\kappa} Z(c_s, 0)
\]

is a local martingale for the reference measure SLE\(_{\kappa}(D, z_0, z)\), \(z\) an auxiliary marked point on the boundary. For short, let us denote SLE\(_{\kappa}(Z)\) obtained by Girsanov transform of the reference SLE\(_{\kappa}(D, z_0, z)\) by \(M\) (up to a disconnection event).
For example, from Lemma 13 it is easy to see that SLEκ(ρ) in \(c = (D, z_0, z_1, \ldots, z_n)\), \(\rho_1 + \cdots + \rho_n = \kappa - 6\), is SLEκ(Z) with:

\[
Z(c) = \prod_{i=1}^{n} H_D(z_i, z_i)^{-\frac{\rho_i}{2\kappa}} \prod_{1 \leq i < j \leq n} H_D(z_i, z_j)^{-\frac{\rho_i \rho_j}{4\kappa}}.
\]

The following is the analogue of Proposition 3.

**Lemma 13.** Let \(c = (D, z_0, z_1, \ldots, z_n)\) be a configuration consisting of a simply connected domain \(D\) with \(n + 1\) marked points on the boundary; \(c' = (D', z_0', z_1', \ldots, z_n')\) is another configuration agreeing with \(D\) in a neighbourhood \(U\) of \(z_0\); \(U\) is at positive distance of marked points other than \(z_0\). Let \(\mu_c^U\) denote the distribution of an SLEκ(Z) in \(c\), stopped upon exiting \(U\). Then:

\[
\frac{\partial \mu_c^U}{\partial \mu_{c'}^U}(\gamma) = \left( \frac{Z(c')Z(c)}{Z(c'_c)Z(c'_c)} \right) \exp(-\lambda m(D; K, D' \setminus D') + \lambda m(D'; K, D' \setminus D'))
\]

where \(c = (D \setminus K, \gamma, z_1, \ldots, z_n)\), similarly for \(c'\).

**Proof.** One can proceed as follows: let \(\mu_c^U\) denotes chordal SLEκ in the configuration \(c\) (aiming at an auxiliary point \(z\)), stopped upon exiting \(U\). Then trivially:

\[
\frac{\partial \mu_c^U}{\partial \mu_{c'}^U} = \frac{\partial \mu_c^U}{\partial \mu_{c}^U} \cdot \frac{\partial \mu_{c'}^U}{\partial \mu_{c'}^U}
\]

The middle term is studied in Proposition 3 while the outer terms are, from the definition of SLEκ(Z):

\[
\frac{d \mu_c^U}{d \mu_{c}^U} = \frac{M_\tau}{M_0} = \frac{Z(c)}{Z(c')} \cdot \frac{H_D(z_0, z)}{H_D(z, \gamma, z)}
\]

where \(\tau\) is the first exit of \(U\), and similarly for the other term. Under the assumptions above, \(M^\tau\) is uniformly bounded (see Lemma 13).

Recall that \(Z(c)\) depends on a choice of local coordinates at the marked points as a 1-form; but the ratio \(\frac{Z(c')Z(c)}{Z(c'_c)Z(c'_c)}\) does not depend on the choices.

### 6.2 A bound on densities

We give an upper bound on Radon-Nikodym derivatives that appear in the coupling argument. This is a rough estimate that is sufficient for our purposes.

A configuration \(c = (D, x, y, z_1, \ldots, z_n)\) consists in a bounded simply connected Jordan domain \(D\), with distinct marked points on its boundary; \(\partial \) (resp. \(\hat{\partial}\)) is the smallest connected boundary arc containing all marked points except \(x\) (resp. \(y\)); \(K\) (resp. \(\hat{K}\)) is a chain growing at \(x\) (resp. \(y\)) generated by the continuous trace \(\gamma\) (resp. \(\hat{\gamma}\)). We denote \(c_{s,t} = (D \setminus (K_s \cup \hat{K}_t), \gamma_s, z_1, \ldots, z_n, \hat{\gamma}_t)\); also \(Z(c) = \psi(c) \prod_{s<t} H_D(z_s, z_t)^{\nu_{s,t}}, \psi\) a positive, continuous, conformally invariant function. For \(0 < s' \leq s, 0 \leq t' \leq t\), define:

\[
\ell_{s', t'} = \left( \frac{Z(c_{s,t})Z(c_{s', t'})}{Z(c_{s', t})Z(c_{s, t'})} \right) \exp(-\lambda m(D \setminus (K_{s'} \cup \hat{K}_{t'}); K_s, \hat{K}_t))
\]

**Lemma 14.** For any \(\eta > 0\) small enough, there exists \(C = C(D, \eta) > 0\) such that for all chains \(K, \hat{K}\), \(0 \leq s' \leq s, 0 \leq t' \leq t\) with \(\text{dist}(K_s, \hat{K}_t) \geq \eta\), \(\text{dist}(K_s, \partial) \geq \eta\), \(\text{dist}(\hat{K}_t, \hat{\partial}) \geq \eta\),

\[C^{-1} < \ell_{s', t'} < C\]
Proof. From the identity: \( \ell_{s',t'} = \ell_{0,0} \ell_{s,t} \ell_{s',t'}^{-1} \), it is enough to prove the bound for \( s' = t' = 0 \). From e.g. Corollary 2.8 in [9], it is enough to prove it in any reference Jordan domain, say the upper semidisk, with all marked points on the segment \((-1,1)\). Also without loss of generality, one can assume there is at least one marked point \( z_1 \).

In the bounded domain \( D \), the total mass of loops of diameter at least \( \eta \) in the loop measure \( \mu^{\text{loop}} \) is finite; this gives uniform bounds above and below for the factor \( \exp(-\lambda n(\ldots)) \).

Consider the set \( S \) of quadruplets \((K,x',\hat{K},y')\) where \( K,\hat{K} \) are compact subsets of \( \overline{D}, K,\hat{K} \) connected, with \( x',y' \) on their respective boundaries, \( \text{dist}(K,\hat{K}) \geq \eta, \text{dist}(K,\partial) \geq \eta, \text{dist}(\hat{K},\partial) \geq \eta \), and \( x' \) (resp. \( y' \)) corresponds to a single prime end on \( D\setminus(K\cup\hat{K}) \). This last condition is always satisfied “at the tip”. The set \( S \) is compact (for Hausdorff convergence of compact subsets of \( \overline{D} \)). To such a quadruplet are associated four configurations: \( c_{0,0} = c, c_{1,0} = (D\setminus K, x',y,z_1,\ldots,z_n), c_{0,1} = (D\setminus \hat{K},x,y',\ldots), c_{1,1} = (D\setminus(K\cup\hat{K}),x',y',\ldots) \).

Then the ratio \( \frac{\mathbb{Z}(c_{11})\mathbb{Z}(c_{00})}{\mathbb{Z}(c_{10})\mathbb{Z}(c_{01})} \) defines a positive function on the compact set \( S \). It is enough to prove that this function is continuous.

Let \((K_n,x'_n,\hat{K}_n,y'_n)\) converge to \((K,x',\hat{K},y')\). By Schwarz reflection across \([-1,1]\) and the Carathéodory convergence theorem ([9], Theorem 1.8), the conformal equivalence \( \phi^n_\infty \) between \( D^n_{11} = D\setminus(K^n\cup\hat{K}_n) \) and \( D_{11} = D\setminus(K\cup\hat{K}) \), extended by reflection and normalized by \( \phi^n_\infty(z_1) = z_1, \phi^n_\infty(z_1) > 0 \), converges locally uniformly away from the unit circle and \((K\cup K\cup K)\) (here \( K \) is the conjugate of \( K \)). The same holds for \( D^n_{00} = D\setminus K_n \) and \( D^n_{01} = D\setminus K_n \).

Fix semidisks \( D(z_i,\eta/2) \) around the marked points \( z_i \)’s; the choice of \( D \) as the upper semidisk gives a choice of local coordinates at the \( z_i \)’s. Then the \( H_{D^n}(z_i,z_j) \) are numbers; they can be decomposed into: excursion harmonic measure in the semidisks \( D(z_i,\eta/2) \), \( D(z_j,\eta/2) \), and the Green function at points on \( C(z_i,\eta/2), C(z_j,\eta/2) \). The excursion harmonic measures are fixed and the Green function converge due to the conformal invariance of the Green function and uniform convergence of the \( \phi^n_\infty \) near the \( z_i \)’s. This proves continuity of the \( H_{D^n}(z_i,z_j) \).

The treatment of ratios of type \( H_{D^n_{11}}(x'_n,z_i)/H_{D^n_{11}}(x'_n,z_j) \) is similar: take a crosscut \( \delta \) at positive distance of \( K \), separating it from \( K \) and the marked points. Then the Poisson excursion kernel can be decomposed w.r.t. the first crossing (by a Brownian motion starting near \( x'_n \)) of \( \delta \) and the last crossing of \( C(z_i,\eta/2) \). It is easy to see that the excursion harmonic measure on \( \delta \) converges. This gives continuity of ratios of type \( H_{D^n_{11}}(x'_n,z_i)/H_{D^n_{11}}(x'_n,z_j) \). Assuming without loss of generality that there are at least 2 marked points \( z_1, z_2 \), the term \( H(x,y) \) can be eliminated from the partition function.

The only remaining thing to check is the convergence of the cross ratios. This is immediate for those not involving \( x, y \), from the convergence of the \( \phi^n_\infty \) as above. This can be done also for those involving \( x, y \); though for our purposes it is enough to prove that all cross-ratios (between marked points) are uniformly bounded. By comparison arguments, it is enough to prove it for cross-ratios involving \( x^-, x^+, y^-, y^+ \) (instead of \( x, y, x', y' \)), where these new points are on \([-1,1]\) and are such that the interval \((x^-, x^+) \) (resp. \((y^-, y^+) \)) contains \( K \cap [-1,1] \) (resp. \( K \cap [-1,1] \)) for \( n \) large enough, and no other marked point. This then reduces to the previous situation.

\[ \square \]

### 6.3 First exit of \( \text{SLE}_\kappa(\rho) \)

We need to establish some simple qualitative properties of \( \text{SLE}_\kappa(\rho) \) in, say, a reference configuration \( c = (\overline{D},0,\infty,z_1,\ldots,z_n) \). In particular, we are interested in the position of the trace the first time a marked point is swallowed.

Assume that \( n = 2, 0 < z_1 < z_2 < \infty \). Then the SLE is well defined up to swallowing of \( z_1 \) at time \( \tau_1 = \tau_{z_1} \). There are several possibilities: \( \tau_1 = \infty; \gamma_{\tau_1} = z_1; \gamma_{\tau_1} \in (z_1,z_2); \gamma_{\tau_1} = z_2; \gamma_{\tau_1} \in (z_2,\infty) \); or \( \gamma_{\tau_1} \)
does not exist. (This last case is unlikely to ever happen, though delicate to rule out in general.)

More precisely, let \( Y_t = \frac{g_t(z_t) - W_t}{g_t(z_2) - W_t} \) and \( ds = \frac{dt}{(g_t(z_2) - W_t)^2} = -\frac{1}{2} d \log g_t'(z_2) \). Then:

\[
dY_s = (1 - Y_s) \left[ \sqrt{\kappa} d B_s + \left( \frac{\rho_1 + 2}{Y_s} + \rho_2 + 2 - \kappa \right) dt \right]
\]

where \( B \) is a standard Brownian motion. This is a diffusion on \([0, 1]\). Notice that \( g_t'(z_2) \) is positive before \( \tau_2 \), and goes to zero at \( t \not\sim \tau_2 \). A scale function of this diffusion is \( F \):

\[
F(y) = \int_{1/2}^{y} u^{-\frac{2}{\kappa}(2 + \rho_1)}(1 - u)^{-\frac{2}{\kappa}(4 + \rho_1 + \rho_2 - \kappa)} du.
\]

It blows up at 0 if \( \rho_1 \geq \frac{\kappa}{2} - 2 \). This means that \( Y \) does not reach 0 in finite time, so that \( \tau_1 = \tau_2 \) a.s. (possibly infinite). If \( \rho_1 < \frac{\kappa}{2} - 2, \rho_1 + \rho_2 \leq \frac{\kappa}{2} - 4 \), the scale function blows up at 1, not 0, meaning that \( \tau_1 < \tau_2 \) a.s.

Assume that the trace has an accumulation point in \([z_1, z_2] \) as \( t \not\sim \tau_2 \). Then \( (Y_t) \) accumulates at 0 as \( t \not\sim \tau_2 \). This can be seen by interpreting \( (g_t(z) - W_t) \) as the limit of the probability divided by \( y \) that a Brownian motion started at \( iy, y \gg 1 \), exits \( \mathbb{H} \setminus K_t \) on the boundary arc \([\gamma_t, z]\). Consider a time where the trace is near an accumulation point in \([z_1, z_2] \). In order to exit on \([\gamma_t, z_1]\), the Brownian motion has to get near \( z_2 \), and then move through a strait where the trace accumulates; this conditional probability is controlled by Beurling’s estimate.

The following lemma gives conditions under which the exit point of an \( \text{SLE}_\kappa(\rho) \) process (first disconnection of a marked point) can be located (at least on a segment). The statement is in terms of accumulation points, which will be enough for our purposes. It is likely that a stronger statement (in terms of limits) holds.

**Lemma 15.** Consider an \( \text{SLE}_\kappa(\rho) \) in \( (\mathbb{H}, 0, \infty, z_1, \ldots, z_n) \), \( 0 < z_1 < \cdots < z_n \). Let \( \overline{p}_k = \rho_1 + \cdots + \rho_k \), \( \overline{p}_n = \kappa - 6 \).

1. Assume that for some \( k \), \( \overline{p}_k \geq \frac{\kappa}{2} - 2 \) for \( i < k \) and \( \overline{p}_k \leq \frac{\kappa}{2} - 4 \) for \( k \leq i < n \). Then a.s. as \( t \not\sim \tau_1 \), \( \gamma_t \) accumulates at \( z_k \) and at no other point in \([z_1, z_n]\).

2. Assume that for some \( k \), \( \overline{p}_k \geq \frac{\kappa}{2} - 2 \) for \( i < k \); \( \overline{p}_k \in (\frac{\kappa}{2} - 4, \frac{\kappa}{2} - 2) \); and \( \overline{p}_k \leq \frac{\kappa}{2} - 4 \) for \( k < i < n \). Then a.s. as \( t \not\sim \tau_1 \), \( \gamma_t \) accumulates at a point in \([z_k, z_{k+1}] \) and at no point in \([z_1, z_n] \setminus [z_k, z_{k+1}] \).

**Proof.** While the results are fairly intuitive from a simple Bessel dimension count, complete arguments are a bit involved.

1. a) Case \( k = n = 2 \). By a change of coordinates, one can send \( z_2 \) to \( \infty \). Then the SLE is defined for all times, \( \tau_1 = \tau_2 = \infty \). This implies that the trace is unbounded (accumulates at \( z_2 = \infty \)). Moreover, for any \( z_3 \in (z_1, z_2) \), the (time changed) diffusion \( Y_t = (g_t(z) - W_t)/(g_t(z_1) - W_t) \) goes to 1 as \( t \not\sim \tau_1 = \infty \), by a study of its scale function. In particular, it does not accumulate at 0; hence the trace does not accumulate in \([z_1, z_3] \). So the only point of accumulation of the trace in \([z_1, z_2] \) is \( z_2 \).

b) Case \( k = n \geq 2 \). Again, we change coordinates so that \( z_n = \infty \). Let \( \rho_1 = \frac{\kappa}{2} - 2 + \rho'_1 \), \( \rho_i = \rho'_i - \rho'_{i-1} \). By assumption, \( \rho'_i \geq 0, i < n \). Consider the SDE (notations as in Lemma [12]):

\[
dZ^1_t = \frac{2}{Z^1_t} dt - \sqrt{\kappa} dB_t + \frac{\rho_i}{Z^i_t} dt = -\sqrt{\kappa} dB_t + \frac{\kappa}{2} dt + \sum_{i=1}^{n-1} \rho'_i \frac{Z^{i+1}_t - Z^i_t}{Z^i_t Z^{i+1}_t} dt
\]

the last sum being nonnegative. By a stochastic domination argument (comparison with a Bessel process, \( \delta = 2 \)), this shows that \( \tau_1 = \infty \). Hence the process is defined for all times and the trace is unbounded.
Next we prove that there is no point of accumulation of the trace in \([z_1, z_{n-1}]\). Take a small neighbourhood \(U\) of \([z_1, z_{n-1}]\). Let \(\sigma_n\) be the first time the trace goes at distance \(n\) (an a.s. finite stopping time). Let \(U_n\) be the connected component of \(U\) in \((g_{\sigma_n}(U) - W_t)/(g_{\sigma_n}(z_{n-1}) - W_t)\). By harmonic measure estimates, it is easy to see that \(U_n\) is contained in an arbitrarily small neighbourhood of \(1\) as \(n \to \infty\), say \(D(1, \varepsilon_n)\). By a), with probability \(1 - o(1)\), an SLE\(_\kappa(\mathbb{H})\) in \((\mathbb{H}, 0, \infty, 1)\) does not intersect \(D(1, \sqrt{\varepsilon_n})\). On the other hand, the density of the SLE\(_\kappa(\mathbb{H})\) starting with all marked points in \(D(1, \varepsilon_n)\) w.r.t. to SLE\(_\kappa(\mathbb{H}_{n-1})\) in \((\mathbb{H}, 0, \infty, 1)\) is \(1 + o(1)\) on the event that the trace does not intersect \(D(1, \sqrt{\varepsilon_n})\). This follows from an inspection of the densities (Lemma 12) and the fact that on the event \(\{\gamma \cap D(0, \sqrt{\varepsilon_n}) = \emptyset\}\), \((g'_1(z)/g'_1(1) - 1)\) is small uniformly in \(t\) and \(z \in [1 - \varepsilon_n, 1 + \varepsilon_n]\). Indeed, Brownian excursions starting from 1 and \(z\) couple with high probability before exiting \(D(1, \sqrt{\varepsilon_n})\).

This proves that with probability \(1 - o(1)\), the original SLE does not return to \(U\) after \(\sigma_n\). Notice that one can insert a point \(z'\) between \(z_{n-1}\) and \(z_n\) with \(\rho_n = 0\) and the result still applies. This shows that there is no point of accumulation in \([z_1, z_n]\).

c) Case \(n = 3, k = 2\). We prove that the trace does not accumulate at \(z_3\) (similarly, at \(z_1\)). By sending \(z_3\) at infinity, it is easy to see that the half-plane capacity of the hull at \(\tau\) seen from \(z_1\) is finite a.s. (one can even compute its Laplace transform). We have to rule out that the hull is unbounded while having finite half-plane capacity. It is enough to prove that the driving process stopped at \(\tau\) stays bounded. Since \(Z_1^1 = g_t(z_1) - W_t\) goes to zero as \(t \uparrow \tau\), it is enough to prove that \(\int_0^\tau \frac{d\tau}{Z_1^1} = \) finite. Consider the SDE for \(Z_1^1\):

\[
dZ_1^1 = -\sqrt{\kappa} dB_t + \frac{\rho_1 + \rho_2 + 2 + \varepsilon_t}{Z_1^1}
\]

where \(\varepsilon_t = \rho_2 (1 - Z_1^1/Z_1^2); \varepsilon_t\) goes to zero as \(t \uparrow \tau\) (by studying the time changed diffusion \((Z_1^1/Z_1^2)\)). One can proceed with a comparison with Bessel processes. On the event \(\{\varepsilon_t \in [0, \varepsilon], t \geq t_0\}\), for \(t \geq t_0\), \(Z_1^1\) is between a Bessel\((\delta - \varepsilon)\) and a Bessel\((\delta)\), \(\delta = 1 + 2(\varepsilon_t + \varepsilon_t') \leq 2 - \frac{\varepsilon}{\kappa}\) (both hit zero in finite time). Let \(t_1\) be the first time the ratio of the two bounding Bessel processes \(X^-\) and \(X^+\) is \(2\); restart them at \(t_1\) from the same position \(Z_1^1\), and define inductively \(t_i, i > 1\). One can think of restarting the majorizing Bessel process at a lower level at \(t_1\) as waiting for the Bessel to reach level \(Z_1^1\). This proves that \(\int_{t_0}^\tau \frac{d\tau}{Z_1^1} \leq 2 \int_{t_0}^{\tau_0} \frac{ds}{X_s^1}\), which is finite.

d) General case. Send \(z_k\) to infinity by a change of coordinate. The conditions on the \(\rho_i\)'s are rephrased as:

\[
\begin{align*}
\rho_1, \rho_1 + \rho_2, \ldots, \rho_1 + \cdots + \rho_{k-1} &\geq \frac{\kappa}{2} - 2 \\
\rho_n, \rho_n + \rho_{n-1}, \ldots, \rho_n + \cdots + \rho_{k+1} &\geq \frac{\kappa}{2} - 2
\end{align*}
\]

Hence the situation to the left and to the right of 0 are identical. It is easy to see from b) that the trace is defined for all times and is unbounded. Let \(\sigma_n\) be the time of first exit of \(D(0, n)\) by \(\gamma\). Rescale the process so that \(g_t(z_1)\) (resp. \(g_t(z_n), W_t\)) is sent to \(-1\) (resp. \(1, W_t\)) at \(t = \sigma_n\). If \(w_t\) is away from \(\pm 1\), one can reason as in b) from the result of c). If \(w\) is close to 1, say, one can rescale by sending \(w\) to 0 (and 1) is fixed. The resulting process has density very close to 1 with a process of type b) as long as \(w_t\) stays close to 1. When \(w_t\) separates from 1, one can apply c) with a density argument.

2. a) Case \(n = 2, k = 1\). It is easily seen by sending \(z_2\) (or \(z_1\)) to infinity that the trace is defined for a finite time. Reasoning as in 1c) shows that the trace is bounded. Hence it accumulates somewhere in \((z_1, z_2)\), but not at \(z_2\) (and by symmetry \(z_1)\).

b) General case. Send \(z_k\) to infinity (so that \(z_{k+1} < 0\)). A stochastic domination argument as in 1b) shows that the driving process is dominated by the one corresponding to \(z_2, \ldots, z_{k-1}\) being sent to infinity while \(z_{k+2}, \ldots, z_n\) are sent to \(z_{k+1}\. It is easily seen that for that process, \(\tau_k < \tau_1\). Consequently, this is also the case for the original process, viz. the trace accumulates on \([z_k, z_n]\) without accumulating on \([z_1, z_k]\). As in 1d), the situation is symmetric, so there is also no accumulation on \((z_{k+1}, z_n]\).
