RATIONAL PARAMETER RAYS OF THE MULTIBROT SETS

DOMINIK EBERLEIN, SABYASACHI MUKHERJEE, AND DIERK SCHLEICHER

Abstract. We prove a structure theorem for the multibrot sets, which are the higher degree analogues of the Mandelbrot set, and give a complete picture of the landing behavior of the rational parameter rays and the bifurcation phenomenon. Our proof is inspired by previous works of Schleicher and Milnor on the combinatorics of the Mandelbrot set; in particular, we make essential use of combinatorial tools such as orbit portraits and kneading sequences. However, we avoid the standard global counting arguments in our proof and replace them by local analytic arguments to show that the parabolic and the Misiurewicz parameters are landing points of rational parameter rays.

1. Introduction

The dynamics of quadratic polynomials and their parameter space have been an area of extensive study in the past few decades. The seminal papers of Douady and Hubbard [DH85, DH82] laid the foundation of subsequent works on the topological and combinatorial structures of the Mandelbrot set, which is indeed one of the most complicated objects in the study of dynamical systems.

In this article, we study the multibrot sets $M_d := \{ c \in \mathbb{C} : \text{The Julia set of } z^d + c \text{ is connected} \}$, which are the immediate generalizations of the Mandelbrot set.

The principal goal of this paper is twofold:

Date: October 27, 2014.
2010 Mathematics Subject Classification. 37F10, 37F20, 37F45, 30D05.
We give a new proof of the structure theorem for the Mandelbrot set consisting of a complete description of the landing properties of the rational parameter rays and the bifurcation of hyperbolic components.

The classical proofs of the structure theorem of the Mandelbrot set can be found in the work of Douady and Hubbard [DH82, DH85], Schleicher [Sch00], and Milnor [Mil00]. While Douady-Hubbard’s proof involves a careful analysis of the Fatou coordinates and perturbation of parabolic points, more elementary and combinatorial proofs were given by Schleicher and Milnor. The non-trivial part of the structure theorem consists of showing that every parabolic and Misiurewicz parameter is the landing point of the required number of rays, which can be detected by looking at the corresponding dynamical plane. Both the combinatorial proofs are carried out by establishing bounds on the total number of parabolic parameters with given combinatorics and showing that at least (Milnor’s proof) or at most (Schleicher’s proof) two periodic parameter rays can land at a parabolic parameter. The present proof follows a suggestion from Milnor and avoids the global counting argument. This is replaced by a combination of the combinatorial techniques of [Sch00] and Milnor [Mil00] (kneading sequences and orbit portraits, respectively) together with a monodromy argument.

We write the proof of the structure theorem in more generality, namely for the multibrot sets. Due to existence of a single critical orbit, the passage from degree two to higher degrees does not add further technical complications. However, one needs to look at the combinatorics more carefully and modify some of the proofs in the higher degree unicritical case.

There has been a growth of interest in the dynamics and parameter spaces of degree $d$ unicritical polynomials (Avila, Kahn and Lyubich [KL05, AKLS09], Milnor [Mil14], Chéritat [Che14]) in the recent years. To our knowledge, there is no written account of the structure theorem for the multibrot sets in the literature and this paper aims at bridging that gap.

It is also worth mentioning that the parameter spaces of unicritical anti-holomorphic polynomials were studied [MNS14, Muk14, HS14, IM14] by some of the authors and several combinatorial and topological differences between the connectedness loci of unicritical polynomials and unicritical anti-polynomials (e.g. discontinuity of landing points of dynamical rays, bifurcation along arcs, non-local connectivity of the connectedness loci, non-trivial accumulation of parameter rays etc.) have been discovered. Hence, the present paper also serves as a precise reference for the corresponding properties in the holomorphic setting which facilitates the comparison between these two families.

The main theorem of this paper is the following:

**Theorem 1.1** (Structure Theorem for Multibrot Sets). For the Multibrot set $\mathcal{M}_d$ and the associated parameter rays the following statements hold:

1. Every periodic parameter ray lands at a parabolic parameter of $\mathcal{M}_d$.
2. Every essential (resp. non-essential) parabolic parameter of $\mathcal{M}_d$ is the landing point of exactly two (resp. one) periodic parameter ray.
3. A periodic parameter ray at some angle $\vartheta$ lands at a parabolic parameter $c$ if and only if, in the dynamics of $f_c$, the dynamical ray at angle $\vartheta$ lands at the parabolic orbit and is one of its characteristic rays.
4. Every pre-periodic parameter ray lands at a post-critically pre-periodic parameter of $\mathcal{M}_d$. 
Every post-critically pre-periodic parameter is the landing point of at least one pre-periodic parameter ray.

A pre-periodic parameter ray at some angle $\vartheta$ lands at a Misiurewicz parameter $c$ if and only if, in the dynamics of $c$, the dynamical ray at angle $\vartheta$ lands at the critical value.

Every hyperbolic component of period greater than one of $\mathcal{M}_d$ has exactly one root and $d - 2$ co-roots and the period one hyperbolic component has exactly $d - 1$ co-roots and no root.

Figure 1. Left: The Mandelbrot set, Right: The multibrot set $\mathcal{M}_4$.

Let us now review some background material and fix our notations. For a general introduction into the field, see [Mil99]. In the following, let $d \geq 2$ be an integer, fixed for the whole paper. Let $f_c(z) = z^d + c$ be a unicritical polynomial of degree $d$ (any unicritical polynomial of degree $d$ can be affinely conjugated to a polynomial of the above form). The set of all points which remain bounded under all iterations of $f_c$ is called the Filled-in Julia set $K(f_c)$. The boundary of the Filled-in Julia set is defined to be the Julia set $J(f_c)$ and the complement of the Julia set is defined to be its Fatou set $F(f_c)$.

We measure angles in the fraction of a whole turn, i.e., our angles are elements of $S^1 \cong \mathbb{R}/\mathbb{Z}$. We define for two different angles $\vartheta_1, \vartheta_2 \in \mathbb{R}/\mathbb{Z}$, the interval $(\vartheta_1, \vartheta_2) \subset \mathbb{R}/\mathbb{Z}$ as the open connected component of $\mathbb{R}/\mathbb{Z} \setminus \{\vartheta_1, \vartheta_2\}$ that consists of the angles we traverse if we move on $\mathbb{R}/\mathbb{Z}$ in anti-clockwise direction from $\vartheta_1$ to $\vartheta_2$. Finally, we denote the length of an interval $I_1 \subset \mathbb{R}/\mathbb{Z}$ by $\ell(I_1) = 1$.

Every $\mathcal{M}_d$ is simply connected and there is a biholomorphic map $\Phi$ from $\mathbb{C} \setminus \mathcal{M}_d$ onto the complement of the closed unit disk $\mathbb{C} \setminus \overline{D}$. The parameter ray with angle $\vartheta$ is defined as the set $\mathcal{R}_\vartheta := \{\Phi^{-1}(r^{2\pi i \vartheta}), r > 1\}$ if $\lim_{r \to 1^+} \Phi^{-1}(r^{2\pi i \vartheta})$ exists, we say that $\mathcal{R}_\vartheta$ lands.

It is well known that for a connected Julia set $J_c$ (i.e. if $c \in \mathcal{M}_d$) the Böttcher map $\phi_c$ maps $\mathbb{C} \setminus K_c$ conformally onto the complement of the closed unit disk $\mathbb{C} \setminus \overline{D}$. For such a $c$ we define the dynamical ray at angle $\vartheta$ by $\mathcal{R}_\vartheta := \{\phi_c^{-1}(r^{2\pi i \vartheta}), r > 1\}$.

For a periodic orbit $\mathcal{O} = \{z_1, z_2, \ldots, z_p\}$ denote by $\lambda(f, \mathcal{O}) := \lambda(f, z) := \frac{d}{dz} f^{\operatorname{op}}(z)$ the multiplier of $\mathcal{O}$. In the case $f = f_c$ we write $\lambda(c, \mathcal{O})$ and $\lambda(c, z)$ instead of $\lambda(f_c, \mathcal{O})$ and $\lambda(f_c, z)$.
We thank John Milnor for fruitful discussions and useful advice. The second author gratefully acknowledges the support of Deutsche Forschungsgemeinschaft DFG during this work. The paper is based on the diploma thesis of the first author in spring 1999 at TUM [Ebe99].

2. Orbit Portraits

Orbit portraits of quadratic complex polynomials were first introduced by John Milnor in his paper [Mil00] as a combinatorial tool to describe the pattern of all periodic external rays landing at different points of a periodic cycle. Milnor proved that any collection of finite subsets of \( \mathbb{Q}/\mathbb{Z} \) satisfying some conditions indeed occur as the orbit portrait of some quadratic complex polynomial. The usefulness of orbit portraits stems from the fact that these combinatorial objects contain substantial information about the connection between the dynamical and the parameter planes.

2.1. Definitions and Properties. In this section, we define orbit portraits for unicritical polynomials of arbitrary degree and prove their basic properties. Finally, we prove an analogous realization theorem for these generalized orbit portraits.

**Definition (Orbit portraits).** Let \( \mathcal{O} = \{z_1, z_2, \cdots, z_p\} \) be a periodic cycle of some unicritical polynomial \( f \). If a dynamical ray \( R_t^f \) at a rational angle \( t \in \mathbb{Q}/\mathbb{Z} \) lands at some \( z_j \); then for all \( j \), the set \( \mathcal{A}_j \) of the angles of all the dynamical rays landing at \( z_j \) is a non-empty finite subset of \( \mathbb{Q}/\mathbb{Z} \). The collection \( \{\mathcal{A}_1, \mathcal{A}_2, \cdots, \mathcal{A}_p\} \) will be called the Orbit Portrait \( \mathcal{P}(\mathcal{O}) \) of the orbit \( \mathcal{O} \) corresponding to the polynomial \( f \).

An orbit portrait \( \mathcal{P}(\mathcal{O}) \) will be called trivial if only one ray lands at each point of \( \mathcal{O} \); i.e. \( |\mathcal{A}_j| = 1, \forall j \). Otherwise, the orbit portrait will be called non-trivial. The portrait \( \mathcal{P} = \{\{0\}\} \) is also called non-trivial.

**Lemma 2.1 (Orientation Preservation).** For any polynomial \( f \), if the external ray \( R_t \) at angle \( t \in \mathbb{R}/\mathbb{Z} \) lands at a point \( z \in J(f) \), then the image ray \( f(R_t) = R_{dt} \) lands at the point \( f(z) \). Furthermore, multiplication by \( d \) maps every \( \mathcal{A}_j \) bijectively onto \( \mathcal{A}_{j+1} \) preserving the cyclic order of the angles around \( \mathbb{R}/\mathbb{Z} \).

**Proof.** Since the ray \( R_t \) lands at \( z \), it must not pass through any pre-critical point of \( f \), hence the same is true for the image ray \( R_{dt} \). Therefore, the image ray is well-defined all the way to the Julia set and continuity implies that it lands at \( f(z) \). For the second part, observe that \( f \) is a local orientation-preserving diffeomorphism from a neighborhood of \( z \) to a neighborhood of \( z_{i+1} \). Hence, it sends the set of rays landing at \( z \) bijectively onto the set of rays landing at \( f(z) \) preserving their cyclic order. \( \square \)

**Lemma 2.2 (Finitely Many Rays).** If an external ray at a rational angle lands at some point of a periodic orbit \( \mathcal{O} \) corresponding to a polynomial, then only finitely many rays land at each point of \( \mathcal{O} \). Moreover, all the rays landing at the periodic orbit have equal period and the ray period can be any multiple of \( p \).

**Remark.** An angle \( t \in \mathbb{R}/\mathbb{Z} \) (resp. a ray \( R_t \)) is periodic under multiplication by \( (d) \) (resp. under \( f \)) if and only if \( t = a/b \) (in the reduced form), for some \( a, b \in \mathbb{N} \) with \( (b, d) = 1 \). On the other hand, \( t \) (resp. \( R_t \)) is strictly pre-periodic if and only if \( t = a/b \) (in the reduced form), for some \( a, b \in \mathbb{N} \) with \( (b, d) \neq 1 \).

**Proof.** This is well-known. See [Mil99] for example. \( \square \)
So far all our discussions hold for general polynomials of degree $d$. Now we want to investigate the consequences of unicriticality on orbit portraits. The next two lemmas are essentially due to Milnor, who proves them for quadratic polynomials in [Mil00].

**Lemma 2.3 (The Critical Arc).** Let $f$ be a unicritical polynomial of degree $d$ and $O = \{z_1, z_2, \cdots, z_p\}$ be an orbit of period $p$. Let $P(O) = \{A_1, A_2, \cdots, A_p\}$ be the corresponding orbit portrait. For each $j \in \{1, 2, \cdots, p\}$, $A_j$ is contained in some arc of length $1/d$ in $\mathbb{R}/\mathbb{Z}$. Thus, all but one connected component of $(\mathbb{R}/\mathbb{Z}) \setminus A_j$ map bijectively to some connected component of $(\mathbb{R}/\mathbb{Z}) \setminus A_{j+1}$ and the remaining complementary arc of $(\mathbb{R}/\mathbb{Z}) \setminus A_j$ covers one particular complementary arc of $A_{j+1}$ $d$-times and all others $(d-1)$-times.

**Proof.** Let $\vartheta \in A_j$. Let $\beta$ be the element of $A_j$ that lies in $[\vartheta, \vartheta + 1/d)$ and is closest to $(\vartheta + 1/d)$. Similarly, let $\alpha$ be the member of $A_j$ that lies in $(\vartheta - 1/d, \vartheta]$ and is closest to $(\vartheta - 1/d)$. Note that there is no element of $A_j$ in $(\beta, \beta + 1/d]$; otherwise the orientation preserving property of multiplication by $(d)$ would be violated. Similarly, $(\alpha - 1/d, \alpha)$ contains no element of $A_j$. Also, the arc $(\alpha, \beta)$ must have length less than $1/d$. We will show that the entire set $A_j$ is contained in the arc $(\alpha, \beta)$ of length less than $1/d$.

![Figure 2. No element of $A_j$ outside $(\alpha, \beta)$.](image)

If there exists some $\gamma \in A_j$ lying outside $(\alpha, \beta)$, then $\gamma \in (\beta + 1/d, \alpha - 1/d)$. Therefore, there exist at least two complementary arcs of $\mathbb{R}/\mathbb{Z} \setminus A_j$ of length greater than $1/d$. Both these arcs cover the whole circle and some other arc(s) of $\mathbb{R}/\mathbb{Z} \setminus A_{j+1}$ under multiplication by $d$. In the dynamical plane of $f$, the two corresponding sectors (of angular width greater than $1/d$) map to the whole plane and some other sector(s) under the dynamics. Therefore, both these sectors contain at least one critical point of $f$. This contradicts the unicriticality of $f$.

This proves that the entire set $A_j$ is contained in the arc $(\alpha, \beta)$ of length less than $1/d$. \qed

**Remark.** Following Milnor, the largest component of $(\mathbb{R}/\mathbb{Z}) \setminus A_j$ (of length greater than $(1 - 1/d)$) will be called the critical arc of $A_j$ and the complementary
component of $A_{j+1}$ that is covered $d$-times by the critical arc of $A_j$, will be called the 
**critical value arc** of $A_{j+1}$. In the dynamical plane of $f$, the two rays corresponding 
to the two endpoints of the critical arc of $A_j$ along with their common landing 
point bound a sector containing the unique critical point of $f$. This sector is called 
a **critical sector**. Analogously, the sector bounded by the two rays corresponding to 
the two endpoints of the critical value arc of $A_{j+1}$ and their common landing point 
contains the unique critical value of $f$. This sector is called a **critical value sector**.

**Lemma 2.4 (The Characteristic Arc).** Among all the complementary arcs of the 
various $A_j$'s, there is a unique one of minimum length. It is a critical value arc 
for some $A_j$ and is strictly contained in all other critical value arcs.

**Proof.** Among all the complementary arcs of the various $A_j$'s, there is clearly at 
least one, say $(t^-, t^+)$, of minimal length. This arc must be a critical value arc for 
some $A_j$: else it would be the diffeomorphic image of some arc of $1/d$ times its 
length. Let $(a, b)$ be a critical value arc for some $A_k$ with $k \neq j$. Both the critical 
value sectors in the dynamical plane of $f$ contain the unique critical value (say, $c$) of 
f. If the external angle of $c$ is $t(c)$, then $t(c) \in (t^-, t^+) \cap (a, b)$. From the unlinking 
property of orbit portraits, it follows that $(t^-, t^+)$ and $(a, b)$ are strictly nested; i.e. 
the critical value sector $(a, b)$ strictly contains $(t^-, t^+)$. \qed

This shortest arc $Z_p$ will be called the **Characteristic Arc** of the orbit portrait 
and the two angles at the ends of this arc will be called the **Characteristic Angles**. 
The characteristic angles, in some sense, are crucial to the understanding of orbit 
portraits.

We are now in a position to give a complete description of orbit portraits of 
unicritical polynomials.

**Theorem 2.5.** Let $f$ be a unicritical polynomial of degree $d$ and $O = \{z_1, z_2, \ldots, z_p\}$ 
be a periodic orbit such that at least one rational dynamical ray lands at some $z_j$. 
Then the associated orbit portrait (which we assume to be non-trivial) $P(O) = \{A_1, A_2, \ldots, A_p\}$ satisfies the following properties:

1. Each $A_j$ is a non-empty finite subset of $\mathbb{Q}/\mathbb{Z}$.
2. The map $\vartheta \rightarrow d\vartheta$ sends $A_j$ bijectively onto $A_{j+1}$ and preserves the cyclic 
order of the angles.
3. For each $j$, $A_j$ is contained in some arc of length less than $1/d$ in $\mathbb{R}/\mathbb{Z}$.
4. Each $\vartheta \in \bigcup_{j=1}^{p} A_j$ is periodic under multiplication by $d$ and have a common 
period $r_p$ for some $r \geq 1$.
5. For every $A_i$, the translated sets $A_{i,j} := A_i + j/d$ ($j = 0, 1, 2, \ldots, d-1$) 
are unlinked from each other and from all other $A_{m}$.

**Proof.** The first four properties follow from the previous lemmas. Property (5) 
simply states the fact that if two rays $R_{\vartheta}^z$ and $R_{\vartheta'}^{z'}$ land together at some periodic 
point $z$, then the rays $R_{\vartheta + j/d}^z$ and $R_{\vartheta' + j/d}^{z'}$ land together at a pre-periodic point $z'$ 
with $f(z') = f(z)$: the Julia set of $f_z$ has a $d$-fold rotation symmetry. \qed

**Definition (Formal Orbit Portraits).** A finite collection $P(O) = \{A_1, A_2, \ldots, A_p\}$ 
of subsets of $\mathbb{R}/\mathbb{Z}$ satisfying the six properties of Theorem 2.5 is called a formal orbit 
portrait.
The condition (3) of Theorem 2.5 implies that each $A_j$ has a complementary arc of length greater than $(1 - 1/d)$ (which we call the critical arc of $A_j$) that, under multiplication by $d$ covers exactly one complementary arc of $A_{j+1}$ $d$-times (which we call the critical value arc of $A_{j+1}$) and the others $(d-1)$-times. We label all the critical value arcs as $I_1, I_2, \cdots, I_p$.

The next lemma is a combinatorial version of Lemma 2.4 and this is where condition (5) of the definition of formal orbit portraits comes in.

**Lemma 2.6.** Let $P(O) = \{A_1, A_2, \cdots, A_p\}$ be a formal orbit portrait. Among all the complementary arcs of the various $A_j$'s, there is a unique one of minimum length. It is a critical value arc for some $A_j$ and is strictly contained in all other critical arcs.

**Proof.** Among all the complementary arcs of the various $A_j$'s, there is clearly at least one, say $I = (t^-, t^+)$, of minimal length $l$. This arc must be a critical value arc of some $A_j$; else it would be the diffeomorphic image of some arc of $1/d$ times its length. Let $I = (a, b)$ be the critical arc of $A_{j-1}$ having length $(d - 1)/d + l/d$ so that its image under multiplication by $d$ covers $(t^-, t^+)$ $d$-times and the rest of the circle exactly $(d - 1)$-times. $(t^-, t^+)$ has $d$ pre-images $I/d, (I/d + 1)/d, (I/d + 2)/d, \cdots, (I/d + (d - 1)/d)$; each of them is contained in $(a, b)$ and has length $l/d$. By our minimality assumption, $(t^-, t^+)$ contains no element of $P$ and hence neither do its $d$ pre-images. Label the $d$ connected components of $\mathbb{R}/\mathbb{Z} \setminus \bigcup_{r=0}^{d-1} (I/d + r/d)$ as $C_1, C_2, \cdots, C_d$ with $C_1 = [b, a]$.

Clearly, $A_{j-1}$ is contained in $C_1$ and the two end-points of $a$ and $b$ of $C_1$ belong to $A_{j-1}$. Also, $C_{i+1} = C_1 + i/d$ for $0 \leq i \leq d - 1$. Therefore, $A_{j-1} + i/d$ is contained in $C_{i+1}$ with the end-points of $C_{i+1}$ belonging to $A_{j-1} + i/d$. By condition (5) of the definition of formal orbit portraits, each $A_{j-1} + i/d$ (for fixed $j$ and varying $i$) is unlinked from $A_k$, for $k \neq j - 1$. This implies that any $A_k$ ($k \neq j - 1$) is contained in int($C_r$), for a unique $r \in \{1, 2, \cdots, d\}$, where $r$ depends on $k$.

Since any $A_k$ ($k \neq j - 1$) is contained in int($C_r$), for a unique $r \in \{1, 2, \cdots, d\}$, all the non-critical arcs of $A_k$ are contained in the interior of the same $C_r$. Thus all the non-critical value arcs of $A_{k+1}$ ($k + 1 \neq j$) are contained $\mathbb{R}/\mathbb{Z} \setminus \{t^-, t^+\}$. Hence the critical value arc of any $A_m$ ($m \neq j$) strictly contains $I = (t^-, t^+)$. The uniqueness follows. \hfill \Box

**Lemma 2.7.** For a formal orbit portrait $P = \{A_1, A_2, \cdots, A_p\}$, multiplication by $d$ either permutes all the rays of $P$ or $|A_j| \leq 2 \forall j$ and the first return map of $A_j$ fixes each angle.

**Proof.** We assume that the cardinality of each $A_j$ is at least three and we'll show that multiplication by $d$ permutes all the rays of $P$. We can also assume that the characteristic arc $I_P$ is a critical value arc of $A_1$. Since $|A_1| \geq 3$, $A_1$ has at least three complementary components. Let $I^+$ be the arc just to the right of $I_P$ and $I^-$ be the one just to the left of $I_P$. Let $I^-$ be longer than $I^+$; i.e. $l(I^-) \geq l(I^+)$. Since $I^+$ is not the critical value arc of $A_1$, there must exist a critical value arc $I_c$ which maps diffeomorphically onto $I^+$ under multiplication by $d$; i.e. $I^+ = (d)^m I_c$, for some $m \geq 1$.

We claim that $I_1 = I_P$. Otherwise, $I_c$ will strictly contain the characteristic arc $I_P$. Since $I_c$ is strictly smaller than $I^+$, $I_c$ cannot contain $I^+$. So one end
of $I_c$ must lie in $I^+$; but then it follows from the unlinking property that both ends of $I_c$ are in $I^+$. Therefore, $I_c$ contains $I^-$. But this is impossible because $l(I^-) \geq l(I^+) \geq l(I_c)$.

Therefore, $I^+ = (d^m)I_P$. Also let, $I^+ = (a, b)$ and $I_P = (b, c)$. Since $I_P$ maps to $I^+$ by an orientation preserving diffeomorphism, we have: $b = d^mc$ and $a = d^mb$. Multiplication by $d^m$ is an orientation preserving map and it sends $A_1$ bijectively onto itself such that the point $b$ is mapped to an adjacent point $a$. It follows that multiplication by $d^m$ acts transitively on $A_1$. Hence multiplication by $d$ permutes all the rays of $P$.

The above dichotomy leads to the following definition:

**Definition** (Primitive and Satellite). If the periods of all angles in $A_1 \cup \ldots \cup A_p$ are equal to $k$, i.e., each angle is fixed by the first return map, then the portrait is called primitive. Otherwise, the orbit portrait is called non-primitive or satellite. In the latter case, all angles are permuted transitively under multiplication by $d$.

We record a few easy corollaries that follow from the proof of the previous lemma.

**Corollary 2.8.** If $P$ is a non-trivial formal orbit portrait, the two characteristic angles are on the same cycle if and only if all angles are on the same cycle.

**Corollary 2.9.** All angles of a formal orbit portrait are on the orbit of at least one of the characteristic angles.

**Corollary 2.10** (Maximality). If $P = \{A_1, A_2, \ldots, A_p\}$ is a non-trivial (formal) orbit portrait, then it is maximal in the sense that there doesn’t exist any other (formal) orbit portrait $P' = \{A'_1, A'_2, \ldots, A'_q\}$ with $A_1 \subseteq A'_1$.

**Proof.** Suppose there exists non-trivial orbit portraits $P$ and $P'$ satisfying the above properties. We will consider two cases and obtain contradictions in each of them.

Let us first assume that $P$ is a primitive orbit portrait. Then $|A_1| = 2$ and the two elements of $A_1$ belong to different cycles under multiplication by $d$. By lemma 2.7, $P'$ must necessarily be an orbit portrait of satellite type and all angles
of $\bigcup_{i=1}^{q} \mathcal{A}'_i$, in particular, the two elements of $\mathcal{A}_1$ must lie in the same cycle under multiplication by $d$: which is a contradiction.

Now suppose $\mathcal{P}$ is an orbit portrait of satellite type; i.e. multiplication by $d$ permutes all the angles of $\mathcal{P}$ transitively. Let, $|\mathcal{A}_1| = v$ (so that the common period of all the angles of $\mathcal{P}$ is $pv$) and $|\mathcal{A}'_1| = v'$ (so that the common period of all the angles of $\mathcal{P}'$ is $qv'$). Since the two portraits have angles in common, it follows that $pv = qv'$. The hypothesis $\mathcal{A}_1 \subseteq \mathcal{A}'_1$ implies that $v' > v$. Therefore, $q < p$. Clearly, both the sets $\mathcal{A}_1$ and $\mathcal{A}_{1+q}$ are contained in $\mathcal{A}'_1$: hence multiplication by $d^p$ would map these two sets onto themselves preserving their cyclic order (multiplication by $d^p$ maps $\mathcal{A}'_1$ onto itself). This forces multiplication by $d^p$ to be the identity map on $\mathcal{A}_1$: a contradiction to the transitivity assumption. □

The next lemma gives a necessary and sufficient condition for the characteristic rays of a formal holomorphic orbit portrait to co-land and is a mild generalization of the corresponding result proved in [M100].

**Lemma 2.11** (Outside The Multibrot Sets). Let $\mathcal{P}$ be a formal holomorphic orbit portrait for $d \geq 2$ and $(t^-, t^+)$ be its characteristic arc. For some $c \notin \mathcal{M}_d$, the two dynamical rays $\mathcal{R}_{t^-}$ and $\mathcal{R}_{t^+}$ (where, $f_c = z^d + c$) land at the same point of $J(f_c)$ if the external angle $t(c) \in (t^-, t^+)$.  

**Proof.** We retain the terminology of lemma 2.6. If $c \notin \mathcal{M}_d$, all the periodic points of $f_c = z^d + c$ are repelling and the Julia set is a Cantor set. Let the external angle of $c$ in the parameter plane be $t(c)$. Label the connected components of $\mathbb{R}/\mathbb{Z} \setminus \{t(c)/d, t(c)/d+1/d, \ldots, t(c)/(d+1)/d\}$ counter-clockwise as $L_0, L_1, \ldots, L_{d-1}$ such that the component containing the angle '0' gets label $L_0$. The $t(c)$-itinerary of an angle $\vartheta \in \mathbb{R}/\mathbb{Z}$ is defined as a sequence $(a_n)_{n\geq 0}$ in $\{0,1, \ldots, d-1\}^\mathbb{N}$ such that $a_n = i$ if $(d)^i \vartheta \in L_i$. All but a countably many $\vartheta$'s (the ones which are not the iterated pre-images of $t(c)$ under multiplication by $d$) have a well-defined $t(c)$-itinerary.

Similarly, in the dynamical plane of $f_c$, the $d$ external rays $\mathcal{R}_{t(c)/d}, \mathcal{R}_{t(c)/d+1/d}, \ldots, \mathcal{R}_{t(c)/(d+1)/d}$ land at the critical point 0 and cut the dynamical plane into $d$ sectors. Label these sectors counter-clockwise as $L'_0, L'_1, \ldots, L'_{d-1}$ such that the component containing the external ray $\mathcal{R}_{t(c)/d}$ at angle '0' gets label $L'_0$. Any point $z \in J(f_c)$ has an associated symbol sequence $(a_n)_{n\geq 0}$ in $\{0,1, \ldots, d-1\}^\mathbb{N}$ such that $a_n = i$ if $f_c^{a\cdot}(z) \in L'_i$. Clearly, a dynamical ray $\mathcal{R}_{t(c)}$ at angle $\vartheta$ lands at $z$ if and only if the $t(c)$-itinerary of $\vartheta$ coincides with the symbol sequence of $z$ defined above.

If $t(c) \in \mathcal{I} = (t^-, t^+)$, the $d$ angles $\{t(c)/d, t(c)/d+1/d, \ldots, t(c)/(d+1)/d\}$ lie in the $d$ intervals $\mathcal{I}/d, (\mathcal{I}/d+1/d), \ldots, (\mathcal{I}/d+(d-1)/d)$ respectively and no element of $\mathcal{P}$ belongs to $\bigcup_{j=0}^{d-1} (\mathcal{I}/d+j/d)$. First note that the rays $\mathcal{R}_{t^-}$ and $\mathcal{R}_{t^+}$ indeed land at $J(f_c)$ as $t(c) \notin \mathcal{F}$ the finite sets $\{t^\pm, dt^\pm, dt^\pm \cdot \cdot \cdot \}$. Each $\mathcal{A}_j$ is contained a unique $C_j$. Therefore, for each $n \geq 0$, the angles $(d)^n t^-$ and $(d)^n t^+$ belong to the same $L_i$. So $t^-$ and $t^+$ have the same $t(c)$-itinerary; which implies that the two characteristic rays $\mathcal{R}_{t^-}$ and $\mathcal{R}_{t^+}$ land at the same point of $J(f_c)$. □
It is now easy to prove the realization theorem for formal orbit portraits.

**Theorem 2.12.** Let $\mathcal{P}(O) = \{A_1, A_2, \cdots, A_p\}$ be a formal orbit portrait for some $d \geq 2$. Then there exists some $c \in C$, such that $f(z) = z^d + c$ has a repelling periodic orbit with associated orbit portrait $\mathcal{P}(O)$.

**Proof.** Let $\mathcal{P} = \{A_1, A_2, \cdots, A_p\}$ be a formal orbit portrait with characteristic arc $\mathcal{I}_\mathcal{P} = (t^-, t^+)$ such that $\{t^-, t^+\} \subseteq A_1$. Choose $c$ outside the Multibrot set $\mathcal{M}_d$ with $t(c) \in (t^-, t^+)$. Then, the two dynamical rays $\mathcal{R}^-_c$ and $\mathcal{R}^+_c$ land at the same point $z \in J(f_c)$. Let $\mathcal{P}' = \{A'_1, A'_2, \cdots, A'_p\}$ be the orbit portrait associated with $O(z)$ such that $\mathcal{A}'_1$ is the set of angles of the rays landing at $z$.

First let’s assume that $|A_j| = 2$ and the first return map (multiplication by $d^p$) of $A_j$ fixes each ray. In this case, $\{t^-, t^+\} = A_1$ and $A_1 \subseteq \mathcal{A}_1'$. By lemma 2.10 we have $\mathcal{P}' = \mathcal{P}$.

On the other hand, if multiplication by $d$ acts transitively on $\mathcal{P}$, there exists $l \in \mathbb{N}$ such that $d^l t^- = t^+$. It follows that $f_{d^l}^p(z) = z$. Since $t^-$ and $t^+$ are adjacent angles in $A_1$, it follows that multiplication by $d^l$ acts transitively on $A_1$ and all the rays in $A_1$ land at $z$. Evidently, $A_1 \subseteq \mathcal{A}_1'$ and once again lemma 2.10 implies that $\mathcal{P}' = \mathcal{P}$. \qed

**Corollary 2.13** (Characteristic Angles Determine Formal Orbit Portraits). Let $\mathcal{P}$ be a non-trivial formal orbit portrait with characteristic angles $t^-$ and $t^+$. Then a formal orbit portrait $\mathcal{P}' = \{A'_1, \cdots, A'_p\}$ equals $\mathcal{P}$ if and only if some $\mathcal{A}'_i$ contains $t^-$ and $t^+$.

**Proof.** Follows from the proof of the previous theorem. \qed

**Remark.** Conversely, it is easy to show that a unicritical polynomial $f_c$ can admit an orbit portrait $\mathcal{P} = \{A_1, A_2, \cdots, A_p\}$ only if $t(c) \in (t^-, t^+)$, where $(t^-, t^+)$ is the characteristic arc of $\mathcal{P}$. Indeed, the characteristic arc must be a critical value arc for some $A_j$ and in the dynamical plane, the corresponding critical value sector bounded by the two rays $\mathcal{R}^-_c$ and $\mathcal{R}^+_c$, together with their common landing point contains the critical value $c$. Therefore the external angle $t(c)$ of $c$ will lie in the interval $(t^-, t^+)$.

**Lemma 2.14** (Characteristic Point). Every periodic orbit with a non-trivial orbit portrait has a unique point $z$, called the characteristic point of the orbit, with the following property: two dynamical rays landing at $z$ separate the critical value from the critical point, from all points of the orbit other than $z$, and from all other dynamical rays landing at the orbit of $z$. The external angles of these two rays are exactly the characteristic angles of the orbit portrait of $z$.

**Proof.** The characteristic rays land at a common point $z$ of the orbit and divide $\mathbb{C}$ into two open complementary components. By definition, one of the domains, say $U_1$ contains exactly the external angles from the characteristic arc $\mathcal{I}_\mathcal{P}$; let the other component be $U_0$. Then clearly the closure $U_0$ must contain all dynamical rays with angles from the portrait, and hence the entire orbit of $z$. The critical value must be contained in $U_1$ (or $U_1$ would have a pre-image bounded by rays from the portrait, yielding a complementary arc of the portrait which was shorter than the characteristic arc). Also, the critical point must be contained in $U_0$. Indeed, if $0$ belonged to $U_1$, then $U_1$ would be a critical sector and $\mathcal{I}_\mathcal{P}$ would be a critical arc of $\mathcal{P}$. But a critical arc has length greater than $(1 - 1/d)$ and $\mathcal{I}_\mathcal{P}$ being
the characteristic arc, has the smallest length amongst all complementary arcs of \( \mathcal{P} \). Clearly, the smallest complementary arc of \( \mathcal{P} \) cannot have length greater than \((1 - 1/d)\). This proves the lemma.

\subsection*{2.2. Stability of Orbit Portraits}

\textbf{Lemma 2.15 (Landing of Dynamical Rays).} For every map \( f_c \) and every periodic angle \( t \) of some period \( n \), the dynamical ray \( \mathcal{R}_1^c \) lands at a repelling periodic point of period dividing \( n \), except in the following circumstances:

1. \( c \in \mathcal{M}_d \) and \( \mathcal{R}_1^c \) lands at a parabolic orbit;
2. \( c \notin \mathcal{M}_d \) is on the parameter ray at some angle \( d^k t \), for \( k \in \mathbb{N} \).

Conversely, every repelling or parabolic periodic point is the landing point of at least one periodic dynamical ray for every \( c \in \mathcal{M}_d \).

\textit{Proof.} This is well known. For the case \( c \in \mathcal{M}_d \), see [Mil99, Theorem 18.10]; if \( c \notin \mathcal{M}_d \), see [GM93, Appendix A]. For the converse, see [Mil99, Theorem 18.11]. □

We should note that for every periodic point \( z_0 \) of \( f_{c_0} \) with multiplier \( \lambda(c_0, z_0) \neq 1 \), the orbit of \( z_0 \) remains locally stable under perturbation of the parameter by the Implicit Function Theorem. With some restrictions this is even true for the associated portrait.

\textbf{Lemma 2.16 (Stability of Portraits).} Let \( c_0 \) be a parameter such that \( f_{c_0} = z^d + c \) has a repelling periodic point \( z_0 \) so that the rays at angles \( A := \{ t_1, \ldots, t_v \} \) \((v \geq 2)\) land at \( z_0 \). Then there exist a neighborhood \( U \) of \( c_0 \) and a unique holomorphic function \( z: U \rightarrow \mathbb{C} \) with \( z(c_0) = z_0 \) so that for every \( c \in U \) the point \( z(c) \) is a repelling periodic point for \( f_c \) and all rays with angles in \( A \) land at \( z(c) \).

Let \( n \) be the common period of the rays in \( A \). Let \( U \) be an open, path connected neighborhood of \( c_0 \) which is disjoint from all parabolic parameters of ray period \( n \) and from all dynamics rays at angles in \( \hat{A} := \bigcup_{j \geq 0} \hat{A}_j \). Then for all parameters \( c \in U \) exactly the rays at angles in \( A \) (and no more) co-land. The same is true at any parabolic parameter of ray period \( n \) on the boundary of \( U \).

\textit{Proof.} The point \( z_0 \) can be continued analytically as a repelling periodic point of \( f_{c_0} \) in a neighborhood of \( c_0 \). By [GM93, Lemma B.1], this orbit will keep its periodic dynamical rays in a neighborhood of \( c_0 \); it might possibly gain extra rays.

Since \( U \) doesn’t intersect any dynamical ray of period \( n \), for all \( c \in A \), the dynamical rays in \( A \) indeed land. Let \( U' \) be the subset of \( U \) where the rays in \( A \) continue to land together. For any \( c \in U' \), the common landing point of the rays in \( A \) must be repelling as \( U \) doesn’t contain any parabolic point of ray period \( n \). By local stability of co-landing rays at repelling periodic points, we conclude that \( U' \) is open in \( U \).

Let \( c \) be a limit point of \( U' \) in \( U \). The external rays at angles in \( A \) do land in the dynamical plane of \( f_c \); we claim that they all co-land. Otherwise, at least two rays at angles \( \vartheta_1 \) and \( \vartheta_2 \) (say) in \( A \) land at two different repelling periodic points in the dynamical plane of \( f_c \) and by implicit function theorem, these two rays would continue to land at different points for all nearby parameters. This contradicts the fact that \( c \) lies on the boundary of \( U' \). Hence, \( U' \) is closed in \( U \). Therefore, \( U' = U \); i.e. the rays in \( A \) co-land throughout \( U \).

Finally, it follows from the maximality property (Lemma 2.10) of non-trivial orbit portraits that no dynamical ray at angle \( \vartheta \notin A \) co-land along with the rays at angles in \( A \). □
The local stability of external rays landing at repelling periodic points is true for arbitrary polynomials (not necessarily unicritical) as well. However, there is a danger that such an orbit gains periodic rays: if for a parameter \( c_0 \) some periodic ray lands at a parabolic orbit, then under small perturbations all continuations of the parabolic orbit may lose the periodic ray, and this ray can land at a different repelling orbit for all sufficiently small (non-zero) perturbations. This actually happens for general cubic polynomials. The previous result shows that such a phenomenon never occurs in the case of unicritical polynomials.

2.3. Wakes. We begin a basic lemma which states that the set of parabolic parameters are isolated.

**Lemma 2.17 (Parabolic Parameters Are Countable).** For \( n \in \mathbb{N} \) the number of parameters with parabolic orbits of ray period \( n \) is finite.

**Proof.** Let \( Q(c, z) := f_c^{\circ n}(z) - z \), considering it as a polynomial in \( z \) whose coefficients are polynomials in \( c \). If \( f_c \) has a parabolic orbit of ray period \( n \), then we have: \( f_c^{\circ n}(z) = z \) and \( \frac{d}{dz}f_c^{\circ n}(z) = 1 \).

In other terms, this reads: \( Q(c, z) = 0 \) and \( \frac{d}{dz}Q(c, z) = 0 \). Therefore, for such a parameter \( c \), \( Q(c, z) \) has a multiple root in \( z \) forcing its discriminant to vanish. The discriminant of \( Q(c, z) \) (viewed as a polynomial in \( z \)) is simply a polynomial in \( c \). Therefore, there are only finitely many such values of \( c \), which finishes the proof. \( \square \)

The previous lemma is false if “ray period \( n \)” is replaced by “orbit period \( n \)”: the boundary of every hyperbolic component of period \( n \) contains a dense set of parabolic parameters with orbit period \( n \).

As a consequence of the previous lemma and the stability of orbit portraits near repelling periodic points, we deduce the fundamental fact that every periodic parameter ray lands.

**Lemma 2.18 (Periodic Parameter Rays Land).** Let \( \vartheta \) be an angle of exact period \( n \) under multiplication by \( d \). Then the parameter ray \( R_{\vartheta} \) lands at a parabolic parameter \( c_0 \) with parabolic orbit of exact ray period \( n \) such that the dynamical ray \( R_{\vartheta}^{n_0} \) lands at a point of the parabolic orbit.

**Proof.** We follow the method of Goldberg and Milnor ([GM93, Theorem C.7]). Let \( P = \{ A_1, \ldots, A_p \} \) be a limit point of the parameter ray \( \mathcal{R}_{\vartheta} \). If the dynamical ray \( \mathcal{R}_{\vartheta}^{n_0} \) landed at a repelling periodic point, then it would continue to do so in a neighborhood \( U \) of \( c \) by Lemma [GM93, Lemma B.1]. But for any parameter on the parameter ray \( \mathcal{R}_{\vartheta} \), this is impossible since for such a parameter, the dynamical ray at angle \( \vartheta \) bounces off a pre-critical point and fails to land. Therefore, by Lemma 2.15 the dynamical ray \( \mathcal{R}_{\vartheta}^{n_0} \) must land at a parabolic periodic point and \( c \) is one of the finitely many parabolic parameters with a parabolic orbit of ray period \( n \) (Lemma 2.17). Since the set of limit points of any ray is connected, the claim follows. \( \square \)

**Theorem 2.19 (Parameter Rays Landing at a Common Point).** Let \( P \) be a non-trivial portrait with characteristic angles \( t^- \) and \( t^+ \). Then the parameter rays \( \mathcal{R}_{t^-} \) and \( \mathcal{R}_{t^+} \) land at a common parabolic parameter.

**Proof.** For \( P = \{ A_1, \ldots, A_p \} \), let \( n \) be the common period of the angles in \( A_1 \cup \ldots \cup A_p \) and let \( F_n \) be the set of all parabolic parameters of ray period \( n \). Consider
the connected components $U_i$ of $\mathbb{C} \setminus \bigcup_{t \in A_1 \cup \ldots \cup A_p} \mathcal{R}_t \cup F_n$. Since $\bigcup A_i$ and $F_n$ are finite (Lemma 2.17) there are only finitely many components and by Proposition 2.18 they are open. By Lemma 2.16 throughout every component $U_i$ the same rays with angles in $A_1 \cup \ldots \cup A_p$ land at common points.

Let $U_1$ be the component which contains all parameters $c$ outside $M_d$ with external angle $t(c) \in (t^-, t^+)$ (there is such a component as $(t^-, t^+)$ does not contain any other angle of $\mathcal{P}$). $U_1$ must have the two parameter rays $\mathcal{R}_{t^-}$ and $\mathcal{R}_{t^+}$ on its boundary. By Theorem 2.12 and Lemma 2.16 each $c \in U_1 \setminus M_d$ has a repelling periodic orbit admitting the portrait $\mathcal{P}$. If the two parameter rays at angles $t^+$ and $t^-$ do not co-land, then $U_1$ would contain parameters $c$ outside $M_d$ with $t(c) \notin (t^-, t^+)$. It follows from the remark at the end of Theorem 2.12 that such a parameter can never admit the orbit portrait $\mathcal{P}$, a contradiction. Hence, the parameter rays $\mathcal{R}_{t^+}$ and $\mathcal{R}_{t^-}$ at the characteristic angles must land at the same point of $M_d$. □

**Definition (Wake).** For an essential portrait $\mathcal{P}$ with characteristic angles $t^-$ and $t^+$, the wake of the portrait (or simply the $\mathcal{P}$-wake of $M_d$) is defined to be the component of $\mathbb{C} \setminus (\mathcal{R}_{t^-} \cup \mathcal{R}_{t^+} \cup \{c_0\})$ not containing 0, where $c_0$ is the common landing point of $\mathcal{R}_{t^-}$ and $\mathcal{R}_{t^+}$.

The wake is well-defined because the parameter 0 can never be on the boundary of the partition.

**Lemma 2.20 (Portrait Realized Only in Wake).** For every non-trivial portrait $\mathcal{P}$, the associated wake is exactly the locus of parameters $c$ for which the map $f_c$ has a repelling orbit with portrait $\mathcal{P}$.

**Proof.** The proof is similar to [Mil00 Theorem 3.1]. □

3. Parameter and Dynamical Rays at the Same Angle

**Definition (Characteristic Point of a Parabolic Orbit).** Let $O$ be a parabolic orbit for some $f_c$. The unique point on this orbit which lies on the boundary of the
bounded Fatou component containing the critical value is defined as the Characteristic point of \( \mathcal{O} \).

It is easy to see that if \( \mathcal{O} \) has a non-trivial orbit portrait, this definition coincides with the one in [2,14].

Consider the parameter ray \( \mathcal{R}_\vartheta \) at a periodic angle \( \vartheta \) with landing point \( c \). We show in this section that the corresponding dynamical ray \( \mathcal{R}_\vartheta^c \) lands at the characteristic point of the parabolic orbit (Theorem 3.3). This proves the Structure Theorem 1.1 in the primitive case (Corollary 3.1) and "half" of the Structure Theorem in the non-primitive case (Lemma 3.8).

The main tool is the concept of orbit separation (Subsection 3.3), which in turn is based on Hubbard trees as introduced in the Orsay Notes [DH85].

3.1. Hubbard Trees. Recall the following fact for a parameter \( c \) with super-attracting orbit: for every Fatou component \( U \) of \( K_c \) there is a unique periodic or pre-periodic point \( z_U \) of the super-attracting orbit and a Riemann map \( \phi_U : U \to \mathbb{D} \) with \( \phi_U(z_U) = 0 \) that extends to a homeomorphism from \( U \) onto \( \mathbb{D} \). Such a map \( \phi_U \) is unique except for rotation around 0. The point \( z_U \) is called the center of \( U \) and for any \( \vartheta \in \mathbb{R}/\mathbb{Z} \) the preimage \( \{ \phi_{U}^{-1}(e^{2\pi i r} \vartheta) : r \in [0,1] \} \) is an internal ray of \( U \) with well-defined landing point. Moreover, since hyperbolic filled-in Julia sets are connected and locally connected, hence arcwise connected [Mil99, Lemmas 17.17 and 17.18], every two different points \( z, z' \in K_c \) are connected by an arc in \( K_c \) with endpoints \( z \) and \( z' \) (an arc is an injective path).

**Definition** (Regular Arc). Let \( c \in \mathcal{M}_d \) be a parameter with super-attracting orbit and \( z, z' \in K_c \). A closed arc \( [z, z'] \) in \( K_c \) is a regular arc if

- \( [z, z'] \) has the endpoints \( z \) and \( z' \),
- for every Fatou component \( U \) of \( f_c \), the intersection \( [z, z'] \cap U \) is contained in the union of at most two internal rays of \( U \) together with their landing points.

We do not distinguish regular arcs which differ by re-parametrization.

**Lemma 3.1** (Regular Arcs). Let \( c \) be a parameter with a super-attracting orbit. Then any two points \( z, z' \in K_c \) are connected by a unique regular arc in \( K_c \).

**Proof.** For the existence of a regular arc \( [z, z'] \), take any arc in \( K_c \) connecting \( z \) to \( z' \). For any bounded Fatou component \( U \) of \( K_c \), it suffices to assume that \( [z, z'] \cap U \) is connected (in fact, this is automatic). It is then easy to modify the arc within \( U \) so as to satisfy the conditions on regular arcs.

For uniqueness, assume that there are two different regular arcs \( [z, z'] \) and \( [z, z']' \) for different points \( z, z' \in K_c \). If \( [z, z'] \neq [z, z']' \), then \( C \setminus (\{z, z'\} \cup \{z, z'\}') \) has a bounded component \( V \) (say) and \( \partial V \) is a simple closed curve formed by parts of the two regular arcs. Since the complement of \( K_c \) is connected, \( V \subset K_c \), so \( V \) is contained within one bounded Fatou component \( U \) of \( K_c \). But now \( \partial V \) must be contained in finitely many internal rays of \( U \) together with their landing points such that two distinct external rays land at the same point: an impossibility. \( \square \)

**Definition** (Hubbard Tree). For \( c \in \mathcal{M}_d \) with super-attracting orbit \( \mathcal{O} \), the Hubbard tree of \( f_c \) is defined as \( \bigcup_{[z, z'] \in \mathcal{O} \times \mathcal{O}} [z, z'] \).
It follows from Lemma 3.1 that every super-attracting map \( f_c \) has a unique Hubbard tree. It is easy to show that this is indeed a finite tree in the topological sense: it has finitely many branch points and no loops.

**Definition** (Branch Points and Endpoints). Let \( c \) be a parameter with a super-attracting orbit \( O \) and associated Hubbard tree \( \Gamma \). For \( z \in \Gamma \) the components of \( \Gamma \setminus \{z\} \) are called branches of \( \Gamma \) at \( z \).

If the number of branches with respect to \( z \) is at least three then \( z \) is called a branch point of \( \Gamma \). If the number is one, then \( z \) is called an endpoint of \( \Gamma \).

**Lemma 3.2** (The Hubbard Tree). Let \( c \neq 0 \) be a parameter with a super-attracting orbit \( O \) and associated Hubbard tree \( \Gamma \). Then \( \Gamma \) intersects the boundary of the Fatou component containing the critical value in exactly one point, which is periodic and the boundary of any other bounded Fatou component in most \( d \) points which are periodic or pre-periodic. In particular, the critical value is an endpoint of the Hubbard tree.

**Proof.** Let \( U_0 \) be the Fatou component containing the critical point and \( U_1, \ldots, U_{n-1} \) the other bounded periodic components such that \( f(U_i) = U_{i+1} \) with \( U_n := U_0 \).

We denote the number of points of intersection of \( \Gamma \) and \( \partial U_i \) by \( a_i \). For two different points \( z, z' \in O \) we consider their regular arc \([z, z']\) and pick \( z^* \in \partial U_l \cap [z, z'] \). Since \( \Gamma \) is unique and invariant, \( f_c(z^*) \in \partial U_{l+1} \cap \Gamma \). This means that the set of intersection points of \( \Gamma \) with the boundary of periodic Fatou components is forward invariant. Since \( f_c : U_l \rightarrow U_{l+1} \) is a one-to-one map for \( l \in \{1, 2, \ldots, n-1\} \) and a \( d \)-to-one map for \( l = 0 \), we have \( 0 < a_0/d \leq a_1 \leq a_2 \leq \cdots \leq a_{n-1} \leq a_0 \).

We show that there is an \( l^* \in \{1, 2, \ldots, n-1\} \) with \( a_{l^*} = 1 \). Indeed, let \( c_l := f_c^l(0) \) be an endpoint of \( \Gamma \). If \( a_l > 1 \), it’s easy to check that there are at least two ways to connect \( c_l \) to the other points on the critical orbit by regular arcs: a contradiction. This along with the previous inequality yields the result.

\[\square\]
Lemma 3.3 (Properties of Branch Points). Let $c$ be a parameter with a super-attracting orbit and associated Hubbard tree $\Gamma$. Consider a $z \in \Gamma$ such that $\Gamma$ has $m$ branches at $z$. Then:

- If $z \neq 0$ then $\Gamma$ has at least $m$ branches at $f_c(z)$.
- If $z = 0$ then $\Gamma$ has exactly one branch at $f_c(z) = c$.
- If $z$ is a branch point then it is periodic or pre-periodic and lies on a repelling or the super-attracting orbit.
- Every point on the critical orbit has at least one and at most $d$ branches.

Proof. The first statement follows from forward invariance of the Hubbard tree, and the second was shown in Lemma 3.2.

This implies the third statement because $\Gamma$ has only finitely many branch points, and all periodic orbits other than the unique super-attracting one are repelling.

The last claim is a restatement of Lemma 3.2. \hfill \Box

3.2. Hyperbolic Components.

Definition (Roots, Co-Roots and Centers). A hyperbolic component $H$ with period $n$ of $M_d$ is a connected component of \{ $c \in M_d : f_c$ has an attracting orbit with exact period $n$ \}.

A root of $H$ is a parameter on $\partial H$ with a non-trivial parabolic orbit of exact ray period $n$ (so that the parabolic orbit disconnects the Julia set). Similarly a co-root of $H$ is a parameter on $\partial H$ with a trivial parabolic orbit of exact ray period $n$ (so that the parabolic orbit does not disconnect the Julia set). A center of $H$ is a parameter in $H$ which has a super-attracting orbit of exact period $n$.

Since our maps $f_c$ have only one critical point, we can see exactly as in the quadratic case [CG93, Chapter VIII, Theorem 1.4] that every hyperbolic component $H$ with period $n$ is a connected component of the interior of $M_d$ and that there is a (non-unique) holomorphic map $z : H \to \mathbb{C}$ such that $z(c)$ is attracting for all $c \in H$ and has exact orbit period $n$.

Moreover, there is a holomorphic multiplier map $\mu : H \to \mathbb{D}$ so that the unique attracting orbit of $f_c$ with $c \in H$ has multiplier $\mu(c)$. Since $|\mu(c)| \to 1$ as $c \to \partial H$, the multiplier map $\mu : H \to \mathbb{D}$ is a proper holomorphic map, hence extends surjectively from $\overline{H}$ to $\overline{\mathbb{D}}$. It follows that every hyperbolic component has (at least) one center and at least one root or co-root (in fact, exactly one center and one root; see Theorems 4.4 and Corollary 4.6). Moreover, we will see in Corollary 4.6 that the number of co-roots of a hyperbolic component is exactly $d - 2$ (if $n \geq 2$). In particular in the quadratic case there are no co-roots.

Lemma 3.4 (In the Neighborhood of Parabolic Parameters). Let $c_0$ be a parabolic parameter with exact parabolic orbit period $k$, exact ray period $n$ and let $z_0$ be a point of the parabolic orbit. Then:

- If the parabolic orbit portrait is non-primitive, then $c_0$ lies on the boundary of hyperbolic components with period $k$ and $n$. Moreover, there exists a neighborhood $U$ of $c_0$ and a holomorphic function $z_1 : U \to \mathbb{C}$ such that $z_1(c)$ is a point of exact period $k$ and $z_1(c_0) = z_0$, and with the following property: for every $c \in U \setminus \{c_0\}$ there is an orbit $\mathcal{O}(c)$ with exact period $n$ that merges into the parabolic orbit $\mathcal{O}(c_0)$ as $c \to c_0$ and for which the multiplier map $c \mapsto \lambda(c, \mathcal{O}(c))$ is holomorphic on $U$. 

If the parabolic orbit portrait is primitive then \( c_0 \) is a root or co-root of a hyperbolic component with period \( n \). Furthermore, there are a two-sheeted cover \( \pi: U' \to U \) of a neighborhood \( U \) of \( c_0 \) with the only ramification point \( \pi(c_0') = c_0 \) and a holomorphic function \( z: U' \to \mathbb{C} \) such that \( z(c') \) is a point of exact period \( n \) and \( z(c'_0) = z_0 \).

**Proof.** The proof for the quadratic case generalizes directly to \( d \geq 2 \) ([Mil00] Lemmas 6.1 and 6.2) and [Sch00] Lemma 5.1). However, for completeness and because our organization differs from the one in [Mil00] and [Sch00], we include the proof here.

The non-primitive case: The multiplier of the parabolic orbit is a root of unity different from 1, so by the Implicit Function Theorem there is a neighborhood \( U \) of \( c_0 \) and a holomorphic function \( z_1: U \to \mathbb{C} \) such that \( z_1(c) \) is a point with exact orbit period \( k \) and \( z_1(c_0) = z_0 \). This implies that the multiplier \( \lambda(c, z_1(c)) \) is a holomorphic function in \( c \) on \( U \). By the Open Mapping Principle and \( |\lambda(c_0, z_1(c_0))| = 1 \) it follows that every neighborhood of \( c_0 \) contains parameters \( c \) such that \( z_1(c) \) is attracting. Thus, \( c_0 \) lies on the boundary of a hyperbolic component with period \( k \).

We now show that it lies also on the boundary of a hyperbolic component with period \( n \): since \( \lambda(f_{c_0}^n, z_0) = 1 \), we obtain \( f_{c_0}^n(z) = z + a(z-z_0)^{q+1} + O((z-z_0)^{q+2}) \) for an integer \( q \geq 1 \), \( a \in \mathbb{C} \), as the Taylor expansion of \( f_{c_0}^n \) near \( z_0 \). It follows from the Leau-Fatou Flower Theorem ([Mil99] Theorem 10.5) that \( z_0 \) has \( q \) attracting petals and that \( f_{c_0}^n \) is the first iterate of \( f_{c_0} \) which fixes them and the (at least \( q \)) dynamical rays landing at \( z_0 \). These rays are permuted transitively by the first return map \( f_{c_0}^k \) (Lemma 3.4), and hence the \( q \) attracting petals are also permuted transitively. Since \( n \) is the least integer with \( \lambda(f_{c_0}^n, z_0) = 1 \), it follows that \( q = n/k \) and \( \lambda(f_{c_0}^k, z_0) \) is an exact \( q \)-th root of \( 1 \). It follows that there are neighborhoods \( U \) of \( c_0 \) and \( V \) of \( z_0 \) such that for every \( c \in U \), \( f_{c}^n(z) \) has exactly \( q + 1 \) fixed points in \( V \), counted with multiplicities. We are interested in the exact periods of these points with respect to \( f_{c} \) for \( c \in U \setminus \{c_0\} \). By the above discussion exactly one of them has exact period \( k \) and no one has a lower period. Since \( \lambda(f_{c_0}^{ql-k}, z_0) \neq 1 \) for \( l = 2, \ldots, q-1 \), it follows that the iterates \( f_{c}^{ql-k} \) have for \( c \in U \) exactly one fixed point in \( V \).

Therefore, \( q \) points in \( V \) have exact period \( n \), and these lie on a single orbit. We thus have for every \( c \in U \setminus \{c_0\} \) an orbit \( O(c) \) with exact period \( n \) and well-defined multiplier such that \( q \) points of \( O(c) \) each coalesce at one point of the parabolic orbit \( O(c_0) \) as \( c \to c_0 \). The multiplier \( c \mapsto \lambda(c, O(c)) \) defines a holomorphic function on \( U \) (One cannot, in general, follow the individual points of the period \( n \) orbit holomorphically. What one can rather follow holomorphically are symmetric functions of the points on the periodic orbit; the multiplier is indeed a symmetric function of the periodic points and it extends holomorphically to \( c \) by Riemann’s removable singularity theorem). As before it follows by the Open Mapping Principle that \( c_0 \) lies on the boundary of a hyperbolic component with period \( n \).

The primitive case: In the primitive case we have again \( \lambda(f_{c_0}^n, z_0) = 1 \) and therefore the Taylor expansion \( f_{c_0}^n(z) = z + a(z-z_0)^{q+1} + O((z-z_0)^{q+2}) \) near \( z_0 \) for an integer \( q \geq 1 \), \( a \in \mathbb{C} \). Since each of the \( q \) petals must absorb a critical orbit and \( f_{c_0} \) has only one, we see \( q = 1 \) and the multiplicity of \( z_0 \) as a root of \( f_{c_0}^n \) is exactly 2. Therefore, it splits into two simple fixed points of \( f_{c_0}^n \) when \( c_0 \) is perturbed. These two fixed points have exact period \( n \) under the original map \( f_{c_0} \).
As \( z \) traverses a small loop around \( c_0 \), these two fixed points might or might not be interchanged (in fact, they are). In any case, they are at their original positions after two loops around \( c_0 \). Hence, on a two-sheeted cover \( U' \) (let the projection map be \( \pi \) so that \( \pi \) is branched only over \( c_0 \)) of a neighborhood of \( c_0 \), the two fixed points can be defined as the values of two holomorphic functions \( z_1(c'), z_2(c') \) with corresponding holomorphic multipliers \( \lambda_1(c'), \lambda_2(c') \) (initially, the functions \( z_i(c') \) are defined on a two-sheeted cover of a punctured neighborhood of \( c_0 \), but the puncture can then be filled in). Since we have \( \lambda_i(\pi^{-1}(c_0)) = +1 \), the Open Mapping Principle implies that there is a parameter \( c_1' \in U' \) with \( c_1 = \pi(c_1') \in M_d \) such that \( |\lambda_1(c_1')| < 1 \). This implies that there is a point \( c_1 \) arbitrarily close to \( c_0 \) with an attracting periodic orbit of exact period \( n \). Thus, \( c_0 \) lies on the boundary of a hyperbolic component of period \( n \). This proves the lemma. \( \square \)

### 3.3. Orbit Separation Lemmas

Now we establish a couple of orbit separation lemmas which will be useful in the sequel. They show the existence of pairs of dynamical rays landing at a common repelling periodic or pre-periodic point which separate certain points within the filled-in Julia set, in the following sense: two points \( z, z' \in K_v \) are separated in the dynamical plane if there are two dynamical rays \( R^c_{\vartheta}, R^c_{\vartheta'} \) landing at a common repelling point \( z_0 \) such that \( z \) and \( z' \) are in different components of \( \mathbb{C} \setminus (R^c_{\vartheta} \cup R^c_{\vartheta'} \cup \{z_0\}) \). It is convenient to call these two rays together with their landing point the ray pair at angles \( (\vartheta, \vartheta') \). One useful feature is that such a co-landing ray pair may be stable even small perturbation when the landing behavior of other dynamical rays is not.

**Lemma 3.5** (Orbit Separation in Super-attracting Case). Suppose that \( f_c \) has a super-attractive orbit of some period \( n \). Then for every two repelling periodic points \( z \) and \( z' \) on the same orbit with non-trivial orbit portrait, there exists a repelling periodic or pre-periodic point \( w \) on a different orbit so that two periodic dynamical rays landing at \( w \) separate \( z \) from \( z' \).

**Proof.** By Lemma 2.14, the characteristic point on the orbit of \( z \) is on the Hubbard tree \( \Gamma \), hence the entire orbit of \( z \) is. Let \( \Gamma' \) be the union of regular arcs between the points on the orbit of \( z \); clearly \( \Gamma' \subset \Gamma \). Let \( \Gamma'' \subset \Gamma \) be the component of \( \Gamma \setminus \{ f_{c}^{-1}(z) \} \) containing the critical point. Then any regular arc in \( \Gamma'' \setminus \Gamma'' \) has its \( f_{c} \)-image in \( \Gamma' \), so any regular arc in \( \Gamma'' \) has its \( f_{c} \)-image in \( \Gamma' \cup [z, c] \) (where \( c \) is the critical value).

Suppose first that \( z \) is the characteristic point of \( z \); then \( z \) is an endpoint of the tree \( \Gamma' \) (similarly as in Lemma 3.2). We may suppose that \( (z, z') \) does not contain any point on the orbit of \( z \). If \( (z, z') \) contains a branch point \( w \) of \( \Gamma' \), then all points on the forward orbit of \( w \) have at least as many branches in \( \Gamma' \) as \( w \), except when the orbit runs through \( z \); in the latter case, the orbit may lose one branch (the branch to the critical value \( c \)), but \( z \) is in fact an endpoint of \( \Gamma' \) and thus cannot be on the orbit of \( w \). Therefore, this branch point \( w \) must be (pre)periodic. If \( w \) is a repelling (pre)periodic point, then it must be the landing point of at least two rational dynamical rays and we are done. If \( w \) lies on the critical orbit (let \( U \) be the periodic Fatou component containing \( w \)), then there must be at least one repelling (pre)periodic point \( w' \) other than \( z \) and \( z' \). Let \( [z, z'] \cap \partial U \) separating \( z \) from \( z' \). As before, \( w' \) must be the landing point of at least two rational dynamical rays. Thus the lemma is proved if \( (z, z') \) contains a branch point of \( \Gamma' \).
We now assume that \((z, z')\) contains no branch point of the tree, and no point on the orbit of \(z\). Let \(n\) be the period of \(z\), and let \(k \in \{1, 2, \ldots, n - 1\}\) be so that \(f^k(z') = z\). If \(f^k\) is injective on \([z, z']\), then \([z, z']\) must contain a (repelling) fixed point of \(f^k\) and the lemma is proved in this case.

Otherwise, there is a minimal \(k' < k < n\) such that \(f^{k'}([z, z']) \ni 0\). Then there is a point \(z'' \in [z, z']\) such that \(f^{k'}([z'', z']) \ni [c, f^{k'}(z')] \ni [z', z]\) is a one-to-one homeomorphism, and again there is a point \(w \in (z, z')\) which is fixed under \(f^{k'}\) (necessarily repelling), so this case is done as well.

In order to treat the case that \(z\) is not the characteristic point of its orbit, it suffices to iterate \(f_c\) until it brings \(z\) to the characteristic point.

**Lemma 3.6** (Orbit Separation Lemma For Two Parabolic Points). Suppose that \(f_c\) has a parabolic orbit. Then for any two parabolic periodic points \(z \neq z'\), there exists a ray pair landing at a repelling periodic or pre-periodic point which separates \(z'\) from \(z\).

**Proof.** It is possible to construct a topological tree (which we call the Parabolic Hubbard tree) in the dynamical plane of the parabolic polynomial \(f_c\) which connects the parabolic orbit and the critical point 0 in a manner analogous to the construction of Hubbard trees for polynomials with super-attracting orbits. The details in the quadratic case can be found in [Sch00, Lemma 3.5]. The characteristic parabolic point (which lies on the boundary of the critical value Fatou component) is an endpoint of this tree and every branch point of the tree is a (pre)periodic repelling point [Sch00, Lemma 3.6].

It suffices to prove the lemma when \(z\) is the characteristic point of the parabolic cycle (otherwise we can iterate \(f_c\) until \(z\) satisfies this condition). We may assume that the part of the parabolic tree between \(z\) and \(z'\) neither traverses a periodic Fatou component except at its ends, nor does it traverse another parabolic periodic point. If there is a branch point of the tree between \(z\) and \(z'\), this branch point must be the landing point of two rational rays separating the orbit and we are done.

Otherwise, we argue as in the previous lemma: let \(n\) be the period of \(z\), and let \(k \in \{1, 2, \ldots, n - 1\}\) be so that \(f^k(z') = z\). Put \(f^k(z) = z''\), then \(f^k\) maps \([z', z]\) onto \([z, z'']\). Since \([z', z]\) contains no branch point of the tree, \([z, z'']\) cannot branch off as well; which implies that there exists \(z^* \in (z', z)\) fixed by \(f^k\). Clearly, \(z^*\) is a repelling periodic point disconnecting the Julia set and hence is the landing point of two rational dynamical rays separating the orbit. This completes the proof of the lemma.

3.4. Results. Now we can show that at least certain rays land pairwise and give a complete description of the periodic rays landing at primitive parabolic parameters.

**Theorem 3.7** (A Necessary Condition). If a periodic parameter ray \(R_\theta\) lands at a parameter \(c_0\), then the dynamical ray \(R^\circ_\theta\) lands at the characteristic point of the parabolic orbit of \(c_0\).

**Proof.** The landing point \(c_0\) of \(R_\theta\) is necessarily parabolic by Theorem 2.11 and the dynamical ray \(R^\circ_\theta\) lands at a point of the parabolic orbit of \(c_0\). Without restriction we assume that the exact parabolic orbit period is at least 2.

Let, \(z\) be the characteristic point on the parabolic cycle. We assume that the dynamical ray \(R^\circ_\theta\) lands at some point \(z'\) of the parabolic orbit where \(z' \neq z\). Then
the Orbit Separation Lemma \((\text{Lemma 3.6})\) shows that there is a rational ray pair at angles \(\vartheta_1, \vartheta_2\) landing at some common (pre)periodic repelling point \(w\) separating \(z\) from \(z'\). In particular, the dynamical ray \(R_{\vartheta_1}^{w_0}\) and the critical value \(w_0\) belong to two different regions of the partition \(\mathbb{C} \setminus R_{\vartheta_1} \cup R_{\vartheta_2}\). For all nearby parameters \(c \approx c_0\), the two parameter rays at angles \(\vartheta_1\) and \(\vartheta_2\) continue to land together \((\text{GM93, Lemma B.1})\) and the partition is stable \((\text{Sch00, Lemma 2.2})\) in following sense: the dynamical ray \(R_{\vartheta_1}^{w_0}\) and the critical value \(w_0\) belong to different regions of this partition in the dynamical plane of \(f_c\). But \(c_0\) is a limit point of the parameter ray \(R_d\) and there are parameters \(c\) arbitrarily close to \(c_0\) such that in the dynamical plane of \(f_c\), the critical value \(c\) lies on the dynamical ray \(R_{\vartheta_1}^{w_0}\); a contradiction. This proves that the landing point of the dynamical ray \(R_{\vartheta_1}^{w_0}\) must be the characteristic point \(z\) on the parabolic orbit.

The next result shows that any parabolic parameter with a non-trivial orbit portrait is the landing point of at least two rational parameter rays.

**Lemma 3.8 (At Least the Characteristic Rays Land at a Parameter).** Every parabolic parameter with a non-trivial portrait is the landing point of the parameter rays at the characteristic angles of the parabolic orbit portrait.

**Proof.** Let \(c\) be a parabolic parameter and denote its parabolic orbit portrait by \(P = \{A_1, \ldots, A_p\}\). Let \(t^-\) and \(t^+\) be the characteristic angles and label the elements of \(P\) cyclically so that \(t^-, t^+ \in A_1\).

By Theorem \((\text{2.19})\) the two parameter rays \(R_{t^-}\) and \(R_{t^+}\) land at a common parabolic parameter \(c'\) (say) with associated wake \(W\) and let \(P' = \{A'_1, \ldots, A'_q\}\) be the orbit portrait of its parabolic orbit. By Theorem \((\text{5.7})\) the dynamical rays \(R_{t^-}^{c'}\) and \(R_{t^+}^{c'}\) land at the same point of the parabolic orbit. There is thus an element in \(P'\) which contains both \(t^-\) and \(t^+\); call this element \(A'_1\). It follows from Lemma \((\text{2.13})\) that \(P = P'\). Therefore, the parabolic parameters \(c\) and \(c'\) have the same parabolic orbit portrait \(P\).

By \(\text{[Mi100, Theorem 4.1]}\) (the quadratic case easily generalizes to unicritical polynomials of any degree), both \(c\) and \(c'\) are limit points of parameters with a repelling periodic orbit with associated orbit portrait \(P\). Now lemma \((\text{2.20})\) tells us that \(c, c' \in \partial W\). This clearly implies that \(c = c'\) and \(c\) is the landing point of the parameter rays at the characteristic angles of the parabolic orbit portrait.

**Lemma 3.9 (Parabolic Parameters with Trivial Portrait).** Let \(c_0\) be a parabolic parameter with a trivial orbit portrait. Then at least one parameter ray lands at \(c_0\).

**Proof.** We continue with the proof of the lemma \((\text{3.4})\) Let \(f_{c_0}\) have a parabolic orbit of period \(n\) and \(z_0\) be a representative point of the parabolic orbit. Then \(z_0\) is a fixed point of multiplicity 2 for the map \(f_{c_0}^n\) and there exists a two-sheeted cover \(U'\) (with a projection map \(\pi\) so that \(\pi\) is branched only over \(c_0\)) of a neighborhood of \(c_0\) such that the two simple fixed points of the perturbed maps can be defined as the values of two holomorphic functions \(z_1(c'), z_2(c')\) with corresponding holomorphic multipliers \(\lambda_1(c'), \lambda_2(c')\). Since we have \(\lambda_1(\pi^{-1}(c_0)) = +1\), the Open Mapping Principle implies that there is a parameter \(c'_1 \in U'\) such that \(c_1 = \pi(c'_1) \in M_d\) and \(|\lambda_1(c'_1)| < 1\) and therefore \(|\lambda_2(c'_1)| > 1\) (there can be at most one non-repelling orbit). Since \(z_2(c'_1)\) is repelling, it is the landing point of at least one periodic dynamical ray (Lemma \((\text{2.15})\); so the corresponding orbit has a portrait \(P \neq \emptyset\). Similarly, there is another parameter \(c'_2 \in U'\) such that \(c_2 = \pi(c'_2) \in M_d\) and
\[|\lambda_2(c'_2)| < 1; \] so no periodic dynamical ray lands at \(z_2(c'_2)\). We may assume that \(U'\) is small enough so that it does not contain parabolic parameters other than \(c_0\) of the same ray period \(n\). Then Lemma 2.16 implies that any path connecting \(c_1\) and \(c_2\) must cross a parameter ray at an angle of period \(n\), which lands at \(c_0\).

Now we can prove the Structure Theorem 1.1 in the primitive case, in particular Statement 2:

**Corollary 3.10 (Parameter Rays Landing at Primitive Parameters).** Let \(c\) be a primitive parabolic parameter. Then \(c\) is the landing point of exactly those parameter rays \(R_\theta\) which land at the characteristic point of the parabolic orbit in the dynamics of \(f_c\). The number of such rays is exactly two if the parabolic orbit is non-trivial, and exactly one otherwise.

**Proof.** We know by Lemma 3.8 and Lemma 3.9: at least two periodic parameter rays land at \(c\) if \(f_c\) has a non-trivial parabolic orbit portrait and at least one periodic parameter ray lands at \(c\) if the associated parabolic portrait is trivial.

By Theorem 3.7, only those parameter rays \(R_\theta\) can land at \(c\) for which the dynamical ray \(R_{c\theta}\) lands at the characteristic point of the parabolic orbit and there are only two (resp. one) such rays available in the primitive case.

The state of affairs is now as follows: every periodic parameter ray lands at a parabolic parameter. Conversely, given a primitive parabolic parameter \(c\), we have shown that it is the landing point of exactly two or one periodic parameter ray(s) depending on whether the parabolic orbit portrait is non-trivial or not. On the other hand, if \(c\) is a non-primitive (satellite) parabolic parameter, then it is the landing point of at least two parameter rays at the characteristic angles of the associated parabolic orbit portrait. Thus it remains to show that a parabolic parameter of satellite type is the landing point of at most two periodic parameter rays. The following two sections will be devoted to the proof of this statement.

4. Roots and Co-Roots of Hyperbolic Components

The goal of this section is to show that every hyperbolic component has exactly one root and exactly \(d - 2\) co-roots.

**Theorem 4.1 (Continuous Dependence of Landing Points on Parameters).** Let \(z_0\) be a repelling or parabolic periodic point of \(f_{c_0}\). For a dynamical ray \(R_{\theta}^{c_0}\) landing at \(z_0\), let \(\Omega(\theta) := \{c \in \mathbb{C} : R_{c\theta}^{c_0} \text{ lands}\}\). Then there is a continuous \(z: \Omega(\theta) \to \mathbb{C}\) such that \(z(c)\) is the landing point of \(R_{c\theta}^{c_0}\).

**Remark.** Although the landing point of the dynamical ray depends continuously on the parameter \(c\) (if the ray lands), the portrait may be destroyed. This is certainly always the case whenever the orbits of the landing points have different periods. For example it may occur that \(z(c)\) splits into several periodic points while perturbing away from a parabolic parameter, among which the rays of the parabolic point are distributed.

**Proof.** The proof is analogous to the one in the quadratic case, see [Sch00, Proposition 5.1].

**Corollary 4.2 (Stability of Portraits in a Hyperbolic Component and its Roots and Co-Roots).** Let \(H\) be a hyperbolic component and \(E\) be the set of all roots and
co-roots of $H$. If $c_0 \in H \cup E$ and $z_0$ be a repelling or parabolic periodic point of $f_{c_0}$, then there is a continuous map $z : H \cup E \to \mathbb{C}$ such that $z(c_0) = z_0$ and the portrait of the orbit of $z(c)$ is the same for all $c \in H \cup E$.

**Proof.** Note that for all $c \in H \cup E$, all periodic dynamical rays land. Hence, their landing points depend continuously on the parameter by Theorem 4.1. In order to prove the corollary, it is enough to show the following: if the dynamical rays, say $R^\circ_0$ and $R_0^\circ$, land at $z_0$ for some $c_0 \in H \cup E$, then $R_0^c$ and $R_0^c$, land together for all $c \in H \cup E$.

Let $z(c)$ and $z(c)'$ be two continuous functions on $H \cup E$ such that $z(c_0) = z(c_0) = z_0$ and $z(c)$ (resp. $z(c)'$) is the landing point of $R_0^c$ (resp. $R_0^c$).

If $z_0$ is a repelling point, then $R_0^c$ and $R_0^c$ continue to land together at repelling periodic points for all $c \approx c_0$. By Lemma 2.10 they co-land throughout $H$; i.e. $z(c) = z(c)' \forall c \in H$. By continuity, $z(c) = z(c)' \forall c \in E$ and we are done.

Now suppose that $z_0$ is a parabolic point. Let $k$ be the orbit period and $n$ the ray period of $z_0$. By Lemma 4.3 points of a $k$-periodic and an $n$-periodic orbit coalesce at $z_0$ and no further orbits are involved. Since one of them is attracting (namely the $n$-periodic orbit in the non-primitive case), $z(c)$ and $z(c)'$ always have period $k$. Since there is only one orbit of period $k$ available, it follows that $z(c) = z(c)'$ for $c \approx c_0, c \in H$. As above, Lemma 2.10 implies that $z(c) = z(c)' \forall c \in H$. By continuity, the same holds at the roots and co-roots. Therefore, $R_0^c$ and $R_0^c$ land together for all $c \in H \cup E$. \qed

**Definition (Multiplier Map of a Hyperbolic Component).** Let $H$ be a hyperbolic component and for $c \in H$ let $\lambda(c, \mathcal{O})$ be the multiplier of the unique attracting orbit of $f_c$. Then the map $\lambda_H : H \to \mathbb{D}, c \mapsto \lambda(c, \mathcal{O})$ is called the multiplier map of $H$.

The multiplier map $\lambda_H$ is well-defined: for hyperbolic parameters there is a unique attracting orbit and the absolute value of the multiplier of an attracting orbit is less than one. Precisely as in the quadratic case we see that the multiplier map $\lambda_H$ of a hyperbolic component $H$ is a proper holomorphic map and has a continuous extension $\lambda_H^{\overline{H}}$ from $\overline{H}$ onto $\overline{D}$.

**Lemma 4.3.** Let $H$ be a hyperbolic component of period $n$ with center $c_0$ and set of roots and co-roots $E (\subset \partial H)$. For any $c \in H \cup E$, there are exactly $(d - 1)$ points on the boundary of the characteristic Fatou component $U_1$ of $f_c$ which are fixed by the first return map of $U_1$. All these periodic points are repelling or parabolic.

**Proof.** Note that for all $c \in H \cup E$, the Julia set $J(f_c)$ is locally connected. Since $U_1$ is simply connected, there exists a Riemann map $\phi : U_1 \to \mathbb{D}$ which extends to a homeomorphism of the closures (this is implied by the local connectivity of $J(f_c)$ and the fact that the filled-in Julia set of $f_c$ is full). Then the first return map $f_c^{n_1}$ of $U_1$ conjugates to a proper degree $d$ holomorphic self-map of $\mathbb{D}$, hence a Blaschke product of degree $d$, say $B_c$. Clearly, the number of points on the boundary of $U_1$ which are fixed by the first return map of $U_1$ is equal to the number of fixed points of $B_c$ on $\partial \mathbb{D}$.

In the (super-)attracting case, there is exactly one fixed point of $B_c$ in $\mathbb{D}$ and by reflection, exactly one fixed point in $\mathbb{C} \setminus \mathbb{D}$. Since a rational map of degree $d$ has $(d + 1)$ fixed points counted with multiplicity, there must be $(d - 1)$ fixed points (counted with multiplicity) on $\partial \mathbb{D}$. Since these fixed points are never parabolic, each of them has multiplicity 1; i.e. there are exactly $(d - 1)$ fixed points of $B_c$ on
\[ \partial \mathbb{D}. \] In the parabolic case, there are no fixed points of \( B_c \) in \( \mathbb{D} \cup ( \mathbb{C} \setminus \mathbb{B} ) \). So all the \((d+1)\) fixed points lie on \( \partial \mathbb{D} \). \( B_c \) has a parabolic fixed point on \( \partial \mathbb{D} \) and the Julia set is all of \( \partial \mathbb{D} \). Clearly, there are two attracting petals; i.e., the parabolic fixed point has multiplicity 3 and there are exactly \((d-2)\) simple fixed points, all distinct. Hence, the total number of distinct fixed points of \( B_c \) on \( \partial \mathbb{D} \) is again \((d-1)\).

Therefore, \( U_1 \) has exactly \((d-1)\) points on its boundary which are fixed by its first return map. Since there can be only one non-repelling periodic orbit of \( c \), these periodic points are either all repelling or exactly one of them is parabolic. \( \square \)

**Lemma 4.4** (On the Boundary of the Characteristic Fatou Component). Let \( H \) be a hyperbolic component of period \( n \) with center \( c_0 \) and set of roots and co-roots \( E (\subset \partial H) \). There are \((d-1)\) continuous functions \( z^{(1)}, \ldots, z^{(d-1)} \) on \( H \cup E \) such that for any \( c \in H \cup E \), \( \{ z^{(1)}(c), \ldots, z^{(d-1)}(c) \} \) are precisely the \((d-1)\) points on the boundary of the characteristic Fatou component \( U_1 \) which are fixed by the first return map of \( U_1 \). At exactly one of them, more than one dynamical rays land. Moreover, at every \( c \in E \), one of the \( z^{(i)}(c) \)'s is the characteristic point of the parabolic orbit.

*Proof.* The super-attracting point \( c_0 \) in the dynamical plane of \( f_{c_0} \) can be holomorphically followed throughout \( H \) yielding an analytic function \( z^* : H \to \mathbb{C} \) with \( z^*(c_0) = c_0 \) and \( z^*(c) \) periodic of period \( n \forall c \in H \). \( z^* \) can be extended to a continuous function on \( H \cup E \) and since the multiplier map \( \lambda^* \) is proper holomorphic on \( \overline{H} \), \( z^*(c) \) must have multiplier 1 for every \( c \in E \). Also, \( z^*(c) \) lies in the closure of the critical value Fatou component for every \( c \in H \cup E \), so it must be the characteristic point of the parabolic orbit for \( c \in E \).

Let the \((d-1)\) points on the boundary of the characteristic Fatou component \( U_1 \) of \( f_{c_0} \) which are fixed by the first return map of \( U_1 \) be \( z^{(1)}_0, \ldots, z^{(d-1)}_0 \). Since the \( z^{(i)}_0 \)'s are repelling, by Corollary 3.4 and 4.2 there are continuous functions \( z^{(i)} \) on \( H \cup E \) with \( z^{(i)}(c_0) = z^{(i)}_0 \) for \( 1 \leq i \leq d-1 \) and the \( z^{(i)}(c) \)'s are repelling for \( c \in H \) such that for any fixed \( i \), the portrait of the orbit of \( z^{(i)}(c) \) remains constant for all \( c \in H \cup E \). Also, each \( z^{(i)}(c) \) lies on the boundary of the characteristic Fatou component of \( f_c \) and is fixed by the first return map of the component. Since \( z^*(c) \) has period \( n \) and lies on the boundary of the characteristic Fatou component of \( c \) for \( c \in E \), it must be one of the points \( z^{(i)}(c) \)'s.

Finally we show that exactly one of the \( z^{(i)}(c) \)'s is the landing point of more than one rays. We first prove the super-attracting case following the proof of [NS03, Lemma 3.4]: without restriction we assume \( n > 1 \) (If \( n = 1 \), the only parameter with a super-attracting fixed point is 0 and the dynamical rays at angles 0 and 1, which we consider as two different rays in this case, land trivially at a common point in the dynamical plane of \( z^d \)). One of the \( z^{(i)}_0 \)'s, say \( z^{(1)}_0 \), lies on the Hubbard tree \( \Gamma \) of \( c_0 \) and it is the only point of \( \Gamma \cap \mathbb{H} \) by Lemma 4.2. Therefore, \( z^{(1)}_0 \) disconnects \( \partial K_c \) and is the landing point of at least two dynamical rays. If there is a second \( z^{(i)}_0 \) \((i \neq 1)\) which disconnects the filled-in Julia set of \( c_0 \), then there must be a periodic or pre-periodic Fatou component \( U' \) which is separated from the characteristic Fatou component by \( z^{(i)}_0 \). Let \( \gamma \) be an injective curve in the filled-in Julia set which connects the critical value to the center of \( U' \) (that is the unique point of \( U' \) which maps onto the critical orbit); \( \gamma \) becomes unique if we require that it maps onto the Hubbard tree by the time that \( U' \) lands on a periodic component.
From then on, all forward iterates of $\gamma$ will be on the Hubbard tree, so they will not meet $z_0^{(i)}$; this is in contradiction to periodicity of $z_0^{(i)}$ and shows that exactly one of the $z_0^{(i)}$’s can disconnect the filled-in Julia set of $c_0$; i.e. exactly one of them (say $z_0^{(1)}$) is the landing point of more than one rays. By Corollary 3.12 only $z^{(1)}(c)$ must be the landing point of more than one dynamical rays for each $c \in H \cup E$. □

**Theorem 4.5** (Mapping Degree of $\lambda_{\overline{\mathcal{M}}}$). The multiplier map $\lambda_{\overline{\mathcal{M}}}$ has mapping degree $d - 1$ and every hyperbolic component $H$ of period greater than one has exactly one root.

**Proof.** Let $H$ be a hyperbolic component with period $n$. The mapping degree of $\lambda_{\overline{\mathcal{M}}}$ is at least $d - 1$: for a center $c_0$ of $H$ there is a holomorphic function $z(c)$ on $H$ such that $z(c_0) = 0$ and we can locally write $\lambda_{\overline{\mathcal{M}}}(c) = d^n f_c^{(n-1)}(z(c))^{d-1} \cdots f_c(z(c))^{d-1} z(c)^{d-1}$. Since $z(c)$ has the only zero at $c_0$, it follows that $\lambda_{\overline{\mathcal{M}}}(c) = d^n (c - c_0)^{d-1} g(c)^{d-1}$ for some non-vanishing holomorphic function $g$ near $c_0$ and $\lambda_{\overline{\mathcal{M}}}$ has mapping degree at least $d - 1$.

The mapping degree is clearly bounded above by the total number of roots and co-roots. By the previous Lemma 4.3, exactly one of the $z^{(i)}$’s becomes the characteristic point of the parabolic orbit at each root or co-root. Fix $i \in \{1, 2, \cdots, d-1\}$; we show that there exists a unique $c \in E$ for which $z^{(i)}(c)$ is the characteristic point of the parabolic orbit. Suppose there was another $c'$ with the same property. Let the orbit portrait of the orbit of $z^{(i)}$ be $\mathcal{P}_i$ which remains constant throughout $H \cup E$ and let $\vartheta$ be a characteristic angle of $\mathcal{P}_i$ (if $\mathcal{P}_i$ is trivial, then $\vartheta$ is the angle of the only dynamical ray landing at the characteristic point $z^{(i)}$). By Lemma 3.8 and Corollary 3.10 the parameter ray at angle $\vartheta$ lands both at $c$ and at $c'$; a contradiction which proves our claim. Therefore, there are only $d - 1$ candidates for parabolic parameters with ray period $n$ on the boundary of $H$ implying that the total number of roots and co-roots of $H$ is at most $d - 1$. Thus, the mapping degree of $\lambda_{\overline{\mathcal{M}}}$ is at most $d - 1$ and hence precisely $d - 1$.

Moreover, this shows that all candidates for characteristic points are realized. Since portraits are stable for all parameters in $H \cup E$ (Corollary 4.4) we obtain by Lemma 4.3 that exactly one parameter in $E$ has a parabolic orbit with a non-trivial orbit portrait. This proves that each hyperbolic component has exactly one root. □

**Corollary 4.6** (Number of Co-Roots). Every hyperbolic component of period greater than one has exactly $d - 2$ co-roots.

The previous two statements, Theorem 4.5 and Corollary 4.6, prove the last assertion of the Structure Theorem.

So far we know that at every hyperbolic component at least $d$ parameter rays land. For the proof of the Structure Theorem it remains to show that at most $d$ parameter rays land at every hyperbolic component. For this purpose we need to connect the landing points of periodic parameter rays landing at a common hyperbolic component by internal rays.

**Definition** (Internal Rays of a Hyperbolic Component). An internal ray of a hyperbolic component $H$ is an arc $c: [0, 1] \to \overline{\mathcal{M}}$ starting at the center such that there is an angle $\vartheta$ with $\lambda_{\overline{\mathcal{M}}}(c) = [0, 1] \cdot e^{2\pi i \vartheta}$. 

Remark. Since \( \lambda_H \) is a \((d - 1)\)-to-one map, an internal ray of \( H \) with a given angle is not uniquely defined. In fact, a hyperbolic component has \((d - 1)\) internal rays with any given angle \( \vartheta \).

5. Kneading Sequences

In this section we complete the description of the landing properties of periodic parameter rays by an induction proof on the ray period, Theorem \ref{thm:induction}. We use a similar strategy as in \cite[Section 3]{Sch00}. However, contrary to the quadratic case, we need for \( d > 2 \) some knowledge on the hyperbolic components, which we accumulated in the previous sections.

**Definition** (Itineraries and Kneading Sequences). Fix \( d \geq 2 \). For an angle \( \vartheta \in \mathbb{R}/\mathbb{Z} \) label the components of \( \mathbb{R}/\mathbb{Z} \setminus \{ \vartheta/d, (\vartheta + 1)/d, \ldots, (\vartheta + (d - 1))/d \} \) in the following manner:

\[
L_\vartheta(\eta) := \begin{cases} 
  m & \text{if } \eta \in \{ (\vartheta + (m - 1))/d, (\vartheta + m)/d \} \\
  (m_1, m_2) & \text{if } \eta = (\vartheta + (m_2 - 1))/d = (\vartheta + m_1)/d
\end{cases}
\]

for some \( m, m_1, m_2 \in \{ 0, 1, \ldots, d - 1 \} \).

The infinite sequence \( I_\vartheta(\eta) := \{ L_\vartheta(\eta), L_\vartheta(d\eta), L_\vartheta(d^2\eta), \ldots \} \) is called the \( \vartheta \)-itinerary of \( \eta \) under the \( d \)-tupling map. We call the special itinerary \( K(\vartheta) := I_\vartheta(\vartheta) = \{ L_\vartheta(\vartheta), L_\vartheta(d\vartheta), L_\vartheta(d^2\vartheta), \ldots \} \) the kneading sequence of \( \vartheta \).

The symbols \((0, 1), (1, 2), \ldots, (d - 2, d - 1), (d - 1, 0)\) are called boundary symbols. Sometimes we replace them by an asterisk (*).

It is convenient to write \( K(\vartheta_1) = K(\vartheta_2) \) for angles \( \vartheta_1, \vartheta_2 \) if both angles have boundary symbols at the same entries and all other symbols coincide.

In the following theorem we define a partition of initial kneading sequences and do most of the proof of the induction step of Theorem \ref{thm:induction}.

**Theorem 5.1** (The Induction Step). Let \( n \geq 2 \) be an integer. Suppose that the root of every hyperbolic component with period \( n - 1 \) or lower is the landing point of exactly two parameter rays. Then any two parameter rays with angles \( \vartheta_1, \vartheta_2 \) of exact ray period \( n \) can land at the same parameter only if \( K(\vartheta_1) = K(\vartheta_2) \).

**Proof.** We claim that there is a partition \( P_{n-1} \) of \( \mathbb{C} \) such that every parameter ray with exact ray period \( n \) together with its landing point is completely contained in an open component of \( P_{n-1} \). Moreover, for any two parameter rays \( R_{\vartheta_1}, R_{\vartheta_2} \) which are both in the same open component of \( P_{n-1} \) the kneading sequences of \( \vartheta_1 \) and \( \vartheta_2 \) coincide in the first \( n - 1 \) entries. Then the theorem follows because any parameter ray at an angle of exact period \( n \) has a kneading sequence of period \( n \) and the \( n \)-th entry of the kneading sequence is (*).

We construct such a partition: let \( \Theta_k \) be the set of all angles with exact period \( k \) and \( A_k \) the set of multiplier maps of the \( k \)-periodic hyperbolic components.

We define \( P_{n-1} := \bigcup_{k=1}^{n-1} \bigcup_{\vartheta \in \Theta_k} R_{\vartheta} \cup \bigcup_{\lambda \in A_k} \lambda^{-1}([0, 1]) \) and assert that \( P_{n-1} \) is a partition with the required properties. By construction \( P_{n-1} \) (together with the components of \( \mathbb{C} \setminus P_{n-1} \)) is a partition of \( \mathbb{C} \). Parameter rays with exact ray period \( k \) land at a parameter which has a parabolic orbit with exact ray period \( k \) (Lemma \ref{lem:parabolic}). For a hyperbolic component \( H \) the inverse image \( \lambda^{-1}([0, 1]) \) is the
set of all internal rays with angle 0. Each of these $d - 1$ internal rays lands at a root or co-root of $H$ and conversely the root and every co-root of $H$ is a landing point of one of these internal rays. It follows that every parameter ray of period $n$ together with its landing point is contained in one of the open components of $\mathbb{C} \setminus P_{n-1}$.

Now assume that two parameter rays $R_{\vartheta_1}, R_{\vartheta_2}$ are both contained in the same open component of $\mathbb{C} \setminus P_{n-1}$. We know that every hyperbolic component has $d - 2$ co-roots and exactly one root. Also by assumption, exactly two (resp. one) parameter ray(s) land at every root (resp. co-root) of hyperbolic components of period $k$, for $k \in \{1, \cdots, n - 1\}$. It follows that on the boundary of every hyperbolic component of period $k$ ($k \in \{1, \cdots, n - 1\}$), exactly $d$ parameter rays of period $k$ land. Thus, for every $k \in \{1, \cdots, n - 1\}$ the number of angles which are in $\Theta_k \cap (\vartheta_1, \vartheta_2)$ is $m \cdot d$ for some $m \in \mathbb{N} \cup \{0\}$. This yields that the $k$-th entry ($k \in \{1, \cdots, n - 1\}$) of $K(\vartheta)$ is incremented $m \cdot d$ times as $\vartheta$ travels from $\vartheta_1$ to $\vartheta_2$. Therefore, $\vartheta_1$ and $\vartheta_2$ have the same kneading sequences. \hfill \Box

**Theorem 5.2** (Different Kneading Sequences). Consider the angles of periodic rays landing at the characteristic point of the parabolic orbit in the dynamical plane of $c_0$, where $c_0$ is a root. Then all these angles have pairwise different kneading sequences, except for possibly the two characteristic angles.

**Proof.** We introduce notations: let $z_1$ be the characteristic point and $R_{\vartheta_1}^{(0)}, \cdots, R_{\vartheta_s}^{(0)}$ the dynamical rays landing at $z_1$. We call the associated orbit portrait $P$. For $s = 2$ there is nothing to prove, so we assume $s \geq 3$ and are automatically in the non-primitive case (Lemma 2.7). Denote the exact period of the angles $\vartheta_1, \cdots, \vartheta_s$ by $n$ and the orbit period of the parabolic orbit by $k = n/s$. Without restriction we assume $k \geq 2$. For $i \in \{1, \cdots, s\}$ denote the $d$ inverse images of $\vartheta_i$ with respect to the $d$-tupling map by $\vartheta_i^{(l)} := (\vartheta_i + l)/d \in S^1$ and the landing point of $\vartheta_i^{(l)}$ by $z_i^{(l)}$, $l \in \{0, \cdots, d-1\}$. The points $z_0^{(0)}, \cdots, z_0^{(d-1)}$ do not depend on the choice of a specific angle $\vartheta_i$ ($i \in \{1, \cdots, s\}$); in fact they are just the pre-images of $z^1$ under $f_{c_0}$. Finally, let $H$ be the hyperbolic component of period $n$ with $c_0 \in \partial H$ and $c_1$ a center of $H$.

By Corollary 4.2 and Lemma 4.3 there are continuous functions $z(0), \cdots, z(d-1)$ on $H \cup \{c_0\}$ such that $z(c_0) = z_0^{(0)}$ and at $z^{(l)}(c)$ land the dynamical rays at the same angles as at $z_0^{(l)}$ for all $i \in \{0, 1, \cdots, d-1\}$ and $c \in H \cup \{c_0\}$. The points $z^{(l)}(c_1)$ lie on the boundary of the critical Fatou component $U_0$ of $f_{c_1}$. Let $\Gamma$ be the Hubbard tree of $c_1$, $U_1$ the characteristic Fatou component and $\gamma$ be the regular arc which connects the unique intersection point $\Gamma \cap \partial U_1$ with the critical value $c_1$. Then $\gamma$ has $d$ inverse images and each of them lies in $\overline{U_0}$ and connects the critical point with one of the points $z^{(l)}(c_1)$. Therefore, $\mathbb{C} \setminus P_{\vartheta_i} (P_{\vartheta_i} := f_{c_1}^{-1}(\gamma) \cup \bigcup_{l=0}^{d-1} R_{\vartheta_i}^{c_1})$ has precisely $d$ open components for each $i \in \{1, 2, \cdots, s\}$. We label the boundary $P_{\vartheta_i}$ by $(\ast)$ and the component containing the critical value $c_1$ by 1. The subsequent components are labelled in anti-clockwise direction. By construction the branch of $\Gamma \setminus U_0$ on which the critical value lies is contained in the component with label 1. Since $f_{c_1}$ is orientation preserving this implies that the label of any branch of $\Gamma \setminus U_0$ does not depend on $P_{\vartheta_i}$. Now it’s easy to see that for a fixed $j \neq k - 1 (\text{mod } k)$, all the dynamical rays at angles $\{d^{j} \cdot \vartheta_i : i = 1, 2, \cdots, s\}$ have the same label with respect to the corresponding partition $P_{\vartheta_i}$. Thus the kneading sequences of the $\vartheta_i$’s can differ only in the $(mk - 1)$-th position, for some $m \in \mathbb{N}$. 

Figure 6. The Julia set of a polynomial $z \mapsto z^3 + c, (c \approx 0.2253 + 0.9414i)$ with a 6-periodic super-attracting orbit (marked in green).

With the notation of the proof, the dynamical rays landing at $z_1$ have angles $\vartheta_1 = 92/728, \vartheta_2 = 100/728$ and $\vartheta_3 = 172/728$. The rays $\vartheta_i^{(l)}$ landing at the three pre-images of $z_1$ are also drawn in.

The kneading sequences of all $\vartheta_i$ except for two angles are pairwise different at an $(mk-1)$-th position: the $(mk-1)$-th entry of the kneading sequence of $\vartheta_i$ is just the label of the ray $R_{c_1^{d(mk-1)} \vartheta_i}$ with respect to the partition $P_{\vartheta_i}$. Let the dynamical rays landing at the parabolic point on the boundary of the critical Fatou component be $\mathcal{S} = \{ R_{\vartheta_1^{(l)}}, R_{\vartheta_2^{(l)}}, \cdots, R_{\vartheta_s^{(l)}} \}$, for some $l \in \{0, 1, \cdots, d-1\}$. Now, $K(\vartheta_i) = K(\vartheta_j)$ only if the number of rays (amongst $\mathcal{S}$) which lie in a given component with label ‘r’ with respect to the partition $P_{\vartheta_i}$ is equal to the number of such rays that lie in the corresponding component with label ‘r’ with respect to the partition $P_{\vartheta_j}$. However, if at least two rays at angles in $\mathcal{S}$ have different labels with respect to $P_{\vartheta_i}$, then the number of rays with the smaller label is different with respect to $P_{\vartheta_i}$ and $P_{\vartheta_j}$ for $i \neq j$. Therefore, all these dynamical rays must have the same label. This is only possible if none of the rays at angles in $\mathcal{S}$ lies in the connected component of $\mathbb{C} \setminus (R_{\vartheta_1^{(l)}} \cup R_{\vartheta_2^{(l)}} \cup z^{(l)}(c_1))$ containing $U_0$, i.e. if $\vartheta_i$ and $\vartheta_j$ are the characteristic angles.

We finish the proof of the Structure Theorem in the periodic case:

**Theorem 5.3** (Precisely Two Parameter Rays Land at Every Root). Every root $c_0$ is the landing point of exactly two parameter rays. The angles of the parameter rays landing at $c_0$ are the characteristic angles of the parabolic orbit of $c_0$.

Proof by induction on the ray period $n$ of $c_0$. For $n = 1$ the only root is the landing point of the parameter rays at angles 0 and 1 that we consider as two rays in this case. Assume that the roots of all hyperbolic components with period $n-1$ or lower
are the landing points of exactly two parameter rays. We obtain by Theorem 5.1 that only the parameter rays at \( n \)-periodic angles with same kneading sequences can land at the root \( c_0 \) of any hyperbolic component with period \( n \). Note that a parameter ray with a given angle can land at \( c_0 \) only if the dynamical ray at the same angle lands at the characteristic point \( z_0 \) of the parabolic orbit (Theorem 5.7) and that the angles of all the dynamical rays landing at \( z_0 \), except possibly for the characteristic angles \( t^- \) and \( t^+ \), have different kneading sequences. Therefore, the only candidates for landing at \( c_0 \) are the two parameter rays at angles \( t^- \), \( t^+ \). By Corollary 3.8, we know that they indeed land at \( c_0 \). This finishes the induction. □

We conclude this section with a proof of the fact that every hyperbolic component has exactly one center.

**Corollary 5.4.** Every hyperbolic component of \( \mathcal{M}_d \) has exactly one center.

**Proof.** We have shown that every hyperbolic component has at least one center. Let the number of super-attracting parameters of period \( n \) in \( \mathcal{M}_d \) be \( c_{d,n} \). For such a parameter, 0 is periodic with exact period \( n \) under \( f_c = z^d + c \). It follows that \( c_{d,n} \) is given by the recursive formula:

\[
c_{d,n} = d^{n-1} - \sum_{k|n,k>1} c_{d,k} - 1 \text{ and } c_{d,1} = 1.
\]

By Theorem 5.4, Corollary 3.10 and Corollary 4.6, exactly \( d \) parameter rays of exact period \( n \) land on the boundary of every hyperbolic component of period \( n \). Let the number of hyperbolic components of period \( n \) in \( \mathcal{M}_d \) be \( s_{d,n} \) and the number of angles of exact period \( n \) under multiplication by \( d \) be \( \sigma_{d,n} \). Then, \( s_{d,n} = \sigma_{d,n}/d \) for \( n > 1 \) and \( s_{d,1} = 1 \) (There is only one super-attracting parameter of period 1 and hence, only one hyperbolic component of period 1). But we know that \( \sigma_{d,n} = d^n - \sum_{k|n,k>1} \sigma_{d,k} - d \) and \( \sigma_{d,1} = d - 1 \). Therefore, \( c_{d,n} = s_{d,n} \forall n \in \mathbb{N} \). Since every hyperbolic component has at least one center, the previous equality shows that the center is unique! □

6. Preperiodic Parameter Rays

In this section, we discuss the landing properties of rational parameter rays at pre-periodic angles. The generalization from quadratic to higher degree case is straight-forward in this case and the proofs are similar to those in [Sch00, Section 4].

**Definition** (Misiurewicz Point). A parameter \( c \) for which the critical orbit is strictly pre-periodic is called a Misiurewicz point.

**Theorem 6.1** (Pre-periodic Parameter Rays Land). Every parameter ray at a pre-periodic angle \( \vartheta \) lands at a Misiurewicz point \( c_0 \). The corresponding dynamical ray \( \mathcal{R}_{\vartheta}^0 \) lands at the critical value \( c_0 \).

**Proof.** See the proof of the pre-periodic case in [Sch00 Theorem 1.1]. □

**Theorem 6.2** (Every Misiurewicz Point is a Landing Point). At every Misiurewicz point a preperiodic parameter ray lands.

**Proof.** See the proof of the pre-periodic case in [Sch00 Theorem 1.1]. □

**Theorem 6.3** (Number of Rays at a Misiurewicz Point). Suppose that a preperiodic angle \( \vartheta \) has preperiod \( l \) and period \( n \). Then the kneading sequence \( K(\vartheta) \) has the same preperiod \( l \), and its period \( k \) divides \( n \). If \( n/k > 1 \), then the total number of
parameter rays at preperiodic angles landing at the same point as the ray at angle \( \vartheta \) is \( n/k \); if \( n/k = 1 \), then the number of parameter rays is 1 or 2.

\textbf{Proof.} See [Sch00, Lemma 4.4].
