HYPOALBUMINEMIA IN MICROSURGICAL FLAPS OF THE MUSCULOSKELETAL APPARATUS

A HIPOALBUMINEMIA EM RETALHOS MICROCIRUÍRGICOS DO APARELHO MUSCULOESQUELÉTICO

ABSTRACT

Objective: To evaluate if the levels of serum total protein and serum albumin are risk factors for surgical complications of free flap limb reconstruction. Methods: Consecutive inclusion of all patients undergoing microsurgical flaps for limb reconstruction of complex injuries. We recorded epidemiological and laboratory data, including total proteins and fractions, for descriptive and analytical statistics. Results: Our study analyzed one microsurgical flap from 35 patients that underwent complex injuries of the limbs. In total, 23 patients were men, and mean age of all patients was 35 years. After statistical analysis, no influence of pre or postoperative hypoalbuminemia was observed on the incidence of complications. Patients with hypoalbuminemia had a higher length of stay than those with normal albumin levels (p = 0.008). Conclusion: We observed 71% of patients had hypoalbuminemia in early postoperative period and we suggest a nutritional support for patients requiring complex traumatic limb reconstruction. Hypoalbuminemia in patients subjected to microsurgical flaps for the treatment of complex traumatic limb injuries did not influence the complications that required surgical reintervention; However, it was associated with prolonged hospital stay. Level of Evidence II, Retrospective study.

Keywords: Free Tissue Flaps. Risk Factors. Hypoalbuminemia. Postoperative Complications.

INTRODUCTION

Acute inflammation is the main indicator of tissue infections and lesions, with leukocytosis and extravasation of plasma proteins from extravascular tissue to the site of infection or injury. Pathophysiological responses such as pyrexia, hormone secretion inhibition, and muscle protein depletion are other reactions of the immune system. Leukocytes and plasma proteins are recruited to the sites of infection and injury, in which they provide immune defense and onset tissue repair. Whereas the concentration of the negative acute phase reactants and albumin reduces, the concentration of plasma proteins entering the inflammatory sites increases, including complement proteins and antibodies. The posttraumatic hypoalbuminemia is...
Microvascular flap reconstruction technique has evolved, reaching excellent outcomes with a reduced incidence of complications. However, the treatment of these injuries in traumatic limb reconstruction still presents higher incidences of complications when compared with the treatment for head, neck, and breast.

General risk factors for flap failure are multiple or extensive trauma, smoking, age, and peripheral vascular disease. Among the perioperative risk factors studied, hypoalbuminemia is a factor that could negatively influence the results of free flap reconstruction. Common causes of free flap failure include arterial and venous thrombosis, infection, anatomic variations, and flap dissection.

In the medical literature, preoperative hypoalbuminemia is identified in poor nutritional conditions and could influence the increase in total flap loss. Studies into the influence of hypoalbuminemia on free flap outcomes have included patients that underwent oncologic reconstruction of the head and neck and breast, in which the patient can have nutritional deficit due to chronic illness, ignoring those subjected to limb reconstruction with microsurgical flaps. Our study sought to evaluate the influence of lower levels of serum total protein and serum albumin in preoperative and postoperative periods in the outcomes of free flap reconstruction of the limbs.

MATERIALS AND METHODS
This is a prospective, cross-sectional study with predefined data collection, approved by the Ethics Committee (CAEE 42679515.2.0000.0068). We performed a consecutive inclusion of all patients who underwent microsurgical flap reconstruction of limbs, performed at a public university hospital. Patients signed an informed consent form. A monitoring protocol was used with the patient’s epidemiological data, pathology-related data and dates of occurrence, as well as clinical follow-up, complication, and end-result data.

The epidemiological data analyzed were sex, age, body mass index (BMI) – in kilograms per square meter (kg/m²), in which obesity was defined when patients achieved a BMI greater than 30 kg/m² – and the presence of comorbidities. We recorded Pre-operative and postoperative laboratory data for hemoglobin (Hb) in grams per deciliter (g/dL), the number of platelets multiplied by 10⁹ per cubic milliliter (× 10⁹/mm³), and levels of serum total protein and serum albumin (g/dL). The cause of the injury that led to the microsurgical procedure was also recorded.

Perioperative data observed were type of flap in relation to the donor area, type of arterial anastomosis, number of venous anastomoses, and ischemia time of microsurgical flap, defined as the time elapsed between clamping of the vessels at the donor site and releasing of the microvascular clamps of the artery and at least one venous anastomosis, obtaining free flap reperfusion.

We described and included complications following the Clavien-Dindo classification grade III, which requires surgical intervention. Complications were dehiscence, partial or total flap loss, thrombosis with indication of revision of anastomoses, and infection.

Regarding laboratory data, the patients had a mean pre-hemoglobin value of 12.21 (± 2.08) g/dL. In the postoperative period, the mean hemoglobin value for the group was 10.65 (± 1.74) g/dL. Eleven patients presented anemia during the preoperative and 12 in the postoperative period.

Analysis of the platelet counts showed that two patients had preoperative thrombocytosis, with a mean value of 326.82 × 10⁹/L (± 125.58 × 10⁹). The level of serum total protein in pre-operative period was 6.16 g/dL on average (± 1.05) and the mean of the level of serum albumin was 3.72 (± 0.89). The mean level of serum total protein in postoperative period was 3.72 (± 0.89).

RESULTS
We included 35 microsurgical flaps, one flap from each patient, for complex injuries of the limbs in a one year period, (September 2018 through September 2019). The mean age of the patients was 35 years (SD 14.11). In total, 12 patients were women and 23 were men. Traumatic injuries accounted for 90% of cases, being motorcycle accident the most common cause of injury, occurring in 55% of the patients.

The anterolateral thigh (ALT) was the most common type of flap, followed by the latissimus dorsi flap (Figures 1 e 2).

### Figure 1. Type of microsurgical flap by donor area. ALT: anterolateral thigh flap.

| Type of flap          | % Cases |
|-----------------------|---------|
| ALT                   | 50%     |
| Medial femoral condyle| 20%     |
| Toe to hand           | 10%     |
| Vascularized fibular flap | 10%    |
| Gracilis              | 10%     |
| Latissimus dorsi      | 5%      |

### Figure 2. Male, 51 years, motorcycle accident with Gustilo IIIB leg open fracture. Patient referred for orthoplastic treatment after 1 month and subjected to a Latissimus Dorsi free flap for coverage.

According to the World Health Organization standard anemia definition. Platelets were divided into values greater than, equal to, or less than 450 × 10⁹/L, according to standardized thrombocytosis values. Values less than 3.4 g/dL were defined as hypoalbuminemia and values less than 6.6 g/dL were defined as hypoproteinemia, according to the tests performed in the same clinical laboratory.
The timing of treatment of complex limb injuries with microsurgical flaps depends on the type of trauma, associated lesions, the referral to the Microsurgery reconstructive Group and the patient’s clinical condition. In our study, 34% of the patients had hypoalbuminemia in pre-operative period, demonstrating that, despite being young adults with a mean age of 35 years, both the severity of the trauma and the delay in referral for definitive microsurgical treatment may lead to a high incidence of malnutrition. We suggest referring to an orthopaedic center for a multidisciplinary treatment at the earliest convenience to avoid protein depletion and complications, as recommended in the literature. Although serum albumin level is considered to be a long-term marker for nutrition status, we observed that, after the free flap surgery for limb reconstruction, the percentage of patients with hypoalbuminemia raised to 71% in early postoperative period. Such increase in protein turnover with a negative whole-body protein balance suggests the monitoring of the patients and a nutritional support for those requiring limb reconstruction with microsurgical flaps in orthopaedic centers. Offodile et al. reported an association between hypoalbuminemia and prolonged hospital stay in patients who underwent free flap treatments. In our study, the patients with hypoalbuminemia had a higher mean length of hospital stay than those with normal albumin levels (28.6 days versus 9.8 days, respectively), with statistical significance (p = 0.008). Therefore, hypoalbuminemia is still associated with higher costs due to prolonged Hospital stay caused by healing delay and infection with clinical treatment in patients with traumatic injuries of the limbs, although the serum albumin level is no longer considered a good marker for malnutrition.

Hypoalbuminemia in patients subjected to microsurgical flaps for treatment of complex traumatic limb injuries is a reference for trauma. Our population is composed of young adults with normal nutritional status. However, the extensive trauma causes protein depletion such as tumors, similar to the occurring in metastasizes, with a p-value of 0.008 using the Mann-Whitney U test. The microsurgical flap success rate was 86%.

DISCUSSION

In situations with great physical stress, such as long surgeries for the treatment of complex limb injuries, the serum albumin level decreases, since it is a negative acute phase reactant and the skeletal tissue is the source for restitution of serum albumin level. The intensity of this stress metabolism depends on the extension of trauma, that initiates an acute inflammation in minutes to hours, thus resulting in post-traumatic protein catabolism that can persist for around four months. A sufficient quantity of proteins is essential for wound healing and immune response; however, the nutritional status of surgical patients is still disregarded, even for oncologic patients.

The nutritional status of surgical patients is an important factor in postoperative complications, including surgical site infection and mortality rates. Malnutrition is associated with prolonged hospital stay and complications due to surgical stress. However, studies on the influence of hypoalbuminemia on outcomes and complications of microsurgical flaps for traumatic limb injuries is scarce, being only available for microsurgical flaps for oncologic reconstructions.

In the Hospital das Clínicas da Faculdade de Medicina, the Reconstructive Microsurgery and Hand Surgery Group focuses on the treatment of complex injuries in the Orthopedic Department, which is a reference for trauma. Our population is composed of young adults with normal nutritional status. However, the extensive trauma causes protein depletion such as tumors, similar to the occurring in patients with chronic diseases. Therefore, it is important to study and monitor the nutritional status of these patients after hospitalization. The timing of treatment of complex limb injuries with microsurgical flaps depends on the type of trauma, associated lesions, the referral to the Microsurgery reconstructive Group and the patient’s clinical condition.
