It is shown that one can stimulate, by using the present-day laboratory magnetic fields, transitions between the $l m$ sub-levels of fast $\mu He^+$ ions forming in muon catalyzed fusion. Strong fields also cause the self-ionization from highly excited states of such muonic ions. Both effects are the consequence of the interaction of the bound muon with the oscillating field of the Stark term coupling the center-of-mass and muon motions of the $\mu He^+$ ion due to the non-separability of the collective and internal variables in this system. The performed calculations show a possibility to drive the population of the $l m$ sub-levels by applying a field of a few Tesla, which affects the reactivation rate and is especially important to the $K\alpha$ x-ray production in muon catalyzed fusion. It is also shown that the $2s - 2p$ splitting in $\mu He^+$ due to the vacuum polarization slightly decreases the stimulated transition rates.

I. INTRODUCTION

We show that using present-day laboratory magnetic fields may change essentially the population of the $l m$ sub-levels of the excited states ($n \geq 2$) of the fast muonic ions $\mu He^+$ forming in muon catalyzed fusion ($\mu CF$)[1-4]. This may affect the muon stripping and, especially, the intensities of the x-rays from the ions. Stronger fields also cause the self-ionization of the highly excited states of the $\mu He^+$ ions.

Both effects are consequences of the non-separability of the collective and internal degrees of freedom of the charged two-body system ($\mu He^+$) in the presence of an external magnetic field. The coupling between the center-of-mass (CM) and light particle (muon) motions is described by an oscillating Stark term which is proportional to the mass ratio $m_\mu/M$ (where $m_\mu$ and $M$ are the muon and the $\mu He^+$ mass respectively), the CM-momentum (see below) and the magnetic field strength $B$. A rather strong coupling of the CM and muon motions due to the essential non-adiabaticity ($m_\mu/M \approx 1/40$) and the high CM-velocity ($v \approx 6v_0 = 6\alpha c, \alpha \approx 1/137$) makes the system $\mu He^+$, formed in $\mu CF$, sufficiently sensitive to the external magnetic field. Thus, as it will be shown below, one can drive the sub-level populations $P_{nlm}$ of the fast $\mu He^+$ in excited states $n \geq 2$ by applying magnetic fields of a few Tesla. However, from the first glance the obtained result looks quite unexpected, because the muonic atomic unit of the magnetic field, $B_0 = (e/\hbar)^3m_\mu^2c \approx 1.01 \cdot 10^{14} G$, is extremely large, exceeding the existing present-day laboratory fields by nine orders of magnitude.

In section II we describe our time-dependent approach for treating the evolution of the two-body charged system in an external magnetic field. The calculations of the transition rates between the sub-levels $l m$ of the fast $\mu He^+$ ion in the presence of a magnetic field are discussed in section III. Section IV is devoted to a discussion of the self-ionization process of highly excited states of the fast $\mu He^+$ ion in a strong field. Finally we provide some conclusions in section V.

II. THEORETICAL APPROACH TO THE FAST MUONIC HELIUM ION IN A MAGNETIC FIELD

We start our analysis with the transformed Hamiltonian of the moving $\mu He^+$ ion in a magnetic field. The Hamiltonian of the system $H = H_0 + h + \Delta U$ consists of two terms describing the CM motion

$$H_0(P, R) = \frac{1}{2M}(P - \frac{Q}{2}B \times R)^2$$

(1)
angular momentum, \(\gamma\) fails to describe correctly a number of interesting phenomena occurring in ion physics. In particular for the non-adiabatic effects in the problem (all the terms of the order \(m\) \(\ll M\) are neglected and the effective Hamiltonian \(H\) is represented by an oscillating Stark field (see Eq.(4)). Thus we get the simplified effective Hamiltonian of the electron system.

Compared to the electronic counterpart \(He\) ions in a magnetic field we suggest an approach including the non-adiabatic effects in the problem (all the terms of the order \(m\) \(\ll M\) are neglected and the effective Hamiltonian \(H\) is represented by an oscillating Stark field (see Eq.(4)). Thus we get the simplified effective Hamiltonian of the electron system.

\[ H(p, r) = \frac{1}{2m_e}(p - eB \times r)^2 + \frac{Qm^2}{2M^2}(M + M_0)B \times r)^2 - ze^2 \]

as well as the coupling term

\[ \Delta U(P, R, r) = \gamma \frac{e}{M} B \times (P - \frac{Q}{2} B \times R) \]

between the CM and internal motions. Here \((R, P)\) and \((r, p)\) are the canonical coordinate-momentum pairs for the CM and internal motions, \(M_0\) is the helium nuclear mass. The magnetic field vector is denoted as \(B\) and oriented along the \(z\)-axis, the charges of the nucleus, the ion and the muon are \(-ze, Q\) and \(e\), respectively and \(\gamma = (M_0 + zm)/M\).

In references \([9,10]\) it was shown that for the one-electron ion \(He^+\) the corrections to the CM motion due to the coupling term (3) are negligible in not too strong fields and at low CM velocities. Therefore, the CM can be treated as a pseudoparticle with mass \(M\) and unit charge \((Q = -e)\) \([9,10]\), performing the cyclic motion

\[ \dot{R} = v_\perp (\cos \omega t n_x - \sin \omega t n_y) \]

with the frequency \(\omega = QB/M\) in the \(xy\)-plane orthogonal to the vector of the magnetic field \(B\). \(v_\perp\) is the projection of the initial CM velocity \(v(t = 0) \equiv \dot{R}(t = 0)\) onto the \(xy\)-plane. By using the classical Hamiltonian equations connecting the CM momentum \(P\) and the velocity \(\dot{R}\) of the center of mass of the \(He^+\) ion in the field \(B\) \([6,7]\), one can transform the mixing term (3) to the form

\[ \Delta U(P, R, r) = \gamma eB \times (\dot{R} + \frac{e\gamma}{M} B \times r) \]

representing an oscillating Stark field (see Eq.(4)). Thus we get the simplified effective Hamiltonian of the electron motion \(H(r, \dot{R}(t))\), with \(\dot{R}(t)\) defined by the Eq.(4). Such an approach has, however, many limitations and in particular fails to describe correctly a number of interesting phenomena occurring in ion physics. In particular for the muonic ion \(\mu He^+\) in a magnetic field the coupling (3) between the internal and CM variables is \(m_e/m_\mu \sim 200\) times stronger compared to the electronic counterpart \(He^+\), what demands an accurate treatment of the non-separability of the system.

For analyzing the time-evolution of the fast \(\mu He^+\) ions in a magnetic field we suggest an approach including the non-adiabatic effects in the problem (all the terms of the order \(m_\mu/M\) and \(m_\mu/M_0\) in Eqs.(1)-(3)). It is a mixed treatment by a coupled system of equations describing quantum mechanically the muon degrees of freedom and treating classically the CM motion. It is formulated as the initial-value problem

\[ i\frac{\partial}{\partial t}\psi(r, t) = H(P(t), R(t), r)\psi(r, t) \]

\[ \psi(r, t = 0) = \phi_{\nu'\nu}m'(r) \]

with the effective Hamiltonian

\[ H(P(t), R(t), r) = -\frac{1}{2m}\Delta r - \frac{2}{r} + \frac{\gamma'}{2m} B \cdot L + \frac{1}{8m}(\gamma'^2 + \frac{4m}{M}\gamma^2)[B \times r]^2 \]

\[ -\gamma \frac{B \times (P(t) - \frac{Q}{2} B \times R(t))]b} \]

depending on the parameters \(P(t)\) and \(R(t)\) defined by the classical Hamiltonian equations of motion

\[ \frac{d}{dt}P_j(t) = -\frac{\partial}{\partial R_j}H_{cl}(P(t), R(t)) \]

\[ \frac{d}{dt}R_j(t) = \frac{\partial}{\partial P_j}H_{cl}(P(t), R(t)) \]

(here \(\phi_{\nu'\nu}m'(r)\) are the Coulomb wave functions of the bound muon in \(\mu He^+\) without external field, \(L\) is the muon angular momentum, \(\gamma' = (M_0^2 - zm_\mu^2)/M^2\) and \(m = m_\mu/(1 + m_\mu/M_0)\)) where the Hamiltonian \(H_{cl}\) is determined as
by averaging the initial Hamiltonian (1-3) over the internal variables \( \mathbf{r} \) at every time moment and simultaneously integration of the coupled Eqs.(6-9). Here and below we use \(-e = \hbar = 1\).

The CM coordinate \( Z \) is separated and two pairs of the classical Hamiltonian equations of motion

\[
\frac{d}{dt} P_x = \frac{\omega}{2} (P_y - \frac{Q B}{2} X + \gamma B(x)) ; \frac{d}{dt} P_y = \frac{\omega}{2} (-P_x - \frac{Q B}{2} Y + \gamma B(y)) ,
\]

\[
\frac{d}{dt} X = \frac{1}{M} P_x + \frac{\omega}{2} Y - \frac{\gamma \omega}{Q} (y) ; \frac{d}{dt} Y = \frac{1}{M} P_y - \frac{\omega}{2} X + \frac{\gamma \omega}{Q} (x)
\]
coupled also with the Schrödinger equation (6) via the terms \( \langle x \rangle = \langle \psi(\mathbf{r}, t) \mid x \mid \psi(\mathbf{r}, t) \rangle \) and \( \langle y \rangle = \langle \psi(\mathbf{r}, t) \mid y \mid \psi(\mathbf{r}, t) \rangle \) need to be integrated.

Such an approach is analogous to the ones given in refs.[11-13] suggested for semiclassically treating the dynamics of molecular processes [12,13]. It has the property of conserving the total energy of the system \( \mu \text{He}^+ \) and includes the coupling between the CM and internal variables, which is important for the problem of a fast muonic ion in a magnetic field due to the essential non-adiabaticity of the system \( (m_\mu/M, m_\mu/M_0 \sim 1/40) \) and high CM-velocity \( (v_\perp \approx 6\alpha c) \).

The time-dependent three-dimensional Schrödinger equation (6) is integrated by the method developed in Refs.[14-16] simultaneously with the system of coupled Hamiltonian equations of motion(10).

In principle one can think also of a time-dependent perturbation theoretical approach in order to describe the sublevel mixing induced by the oscillating motional electric field. However, the large center of mass velocity together with the strong non-adiabaticity in the case of our muonic helium would certainly require a very careful estimate of the possible range of validity of such an approach. For small center of mass velocities of the “electronic” \( \text{He}^+ \)-ion a perturbation theoretical approach for the classical dynamics of the ion has been developed in Ref. [17].

III. TRANSITIONS BETWEEN SUB-LEVELS \( LM \) OF FAST MUONIC HELIUM IONS IN A MAGNETIC FIELD

The fast ions \( \mu \text{He}^+ \) are formed in \( \mu \text{CF} \) due to the muon “sticking” process to helium

\[
dt \mu \rightarrow \mu^4 \text{He} + n \tag{11}
\]

partly in excited states \( n \geq 2 \) with the kinetic energy \( E_{cm} = Mv^2/2 \approx 3.5 MeV \)[1-4,14]. At the present time the effect is rather well investigated both experimentally and theoretically due to its importance for the efficiency of \( \mu \text{CF} \) in deuterium-tritium mixture [3]. Particularly an essential dependence of the muon “stripping” from the \( \mu \text{He}^+ \) ions (characterized by the reactivation rate \( R \) in 1514) on the population \( P_{nlm} \) of its excited states \( (nl \neq 1s) \)[18-21] was found. Here we analyze this parameter in the presence of an external magnetic field.

We have calculated the time evolution of the population

\[
P_{nl}(t) = \sum_{m=-l}^{l} \mid \langle \phi_{nlm}(\mathbf{r}) \mid \psi(\mathbf{r}, t) \rangle \mid^2 \tag{12}
\]

of the sub-levels \( l \) for states \( n = 2 \) and \( 3 \) of \( \mu \text{He}^+ \) for the present-day laboratory fields \( B \) with strengths of a few Tesla. The maximal value \( v_\perp = 6v_0 = 6\alpha c \) of the \( \mu \text{He}^+ \) ion CM velocity projection onto the \( xy \)-plane, perpendicular to the direction of the magnetic field \( \mathbf{B} \), is chosen to coincide with the initial velocity of the ion, \( v \approx 6v_0 \ (E_{cm} = Mv^2/2 \approx 3.5 MeV) \), forming in reaction (11).

The coupled Schrödinger equation (6) and classical equations (10) with the initial conditions

\[
\psi(\mathbf{r}, t = 0) = \phi_{nlm}(\mathbf{r}),

P_x(t = 0) = Mv_\perp , P_y(t = 0) = 0 ,

X(t = 0) = Y(t = 0) = 0 ,
\]

were integrated simultaneously with the same step of integration \( \Delta t \) over time \( t \). Details of the computational scheme applied for the integration of the Schrödinger equation (6) can be found in refs. [13,14]. The grids over \( r \in [0,r_m = 400a_0] \) (250 grid points) and the angular variables \( \{\theta, \phi\} \) (25 grid points) were constructed according to ref. [15]. The step of integration over \( t \) was chosen as \( \Delta t \leq 2 \cdot 10^3 t_0 \), what permitted to keep the accuracy of the
the reactivation rates \( \mu CF \) makes it possible to analyze directly the influence of the driving magnetic field to the intensity, are under extensive experimental investigation so far \([3, 20, 21, 28]\). Thus, the experimental achievement in The possibility to create a well-defined mixing of the \( K \) influence of these populations on the reactivation rate \( R \) in the process of the deceleration in a dense deuterium-tritium mixture (transitions due to inelastic collisions, Auger transitions, Stark mixing \([18, 19, 25, 26]\)). Transitions between different \( s \) sub-levels in excited states \([18, 19]\) due to a considerable variation for the estimates of the \( 2s \) depopulation due to the relativistic \( 2s \) transitions occur through energy transfer from the CM to the internal muon motion among other relativistic and short-range corrections in the muonic helium \([24]\). Muonic ions (atoms) are much more
demonstrated by solving the classical equations of motion for Rydberg states of the one-electron \( He^+ \) ion. Here we discuss briefly the possibility to ionize the fast highly-excited \( \mu He^+ \) ion by a strong magnetic field. Actually, the evaluated quantities \( (12) \) about a few percents after \( 10^5 - 10^6 \) steps of integration. Here and below some values are given in muonic atomic units of \( a_0 = \hbar^2/(m_\mu e^2) = 2.56 \cdot 10^{-11} cm \) and \( t_0 = \hbar^3/(m_\mu e^4) = 1.17 \cdot 10^{-19} s \).

Results of the calculation are presented in Figs.1 and 2. We have analyzed two cases: the muon is initially in the \( 2s \) or \( 3s \) states of \( \mu He^+ \), i.e. the quantum numbers \( n'l'm' \) were fixed as 200 or 300 in Eqs.(13). The obtained data demonstrate that applying the magnetic fields of the order of a few Teslas stimulates fast transitions between the \( lm \) sub-levels in excited states \( (n \geq 2) \) of the \( \mu He^+ \) ions moving with the velocities defined by the energy output in the fusion reaction \((11)\). These transitions occur through energy transfer from the CM to the internal muon motion and become faster with increasing field strength \( B \) or the \( v_\perp \) component of the initial CM velocity \( v \) (see Figs.2) in agreement with the classical equations

\[
\frac{d}{dt} E_{cm} = - \frac{d}{dt} E_{int} = e\gamma (B \times \dot{R}) \dot{r},
\]

where \( E_{cm} \) and \( E_{int} \) are the energy of the center of mass and internal motion respectively. This equation is the consequence of the classical Hamiltonian equations of motion of the two-body charged system in a magnetic field and shows a permanent exchange of energy between the CM and muonic degrees of freedom.

The above results were obtained in the nonrelativistic limit for which the splitting between different \( lm \) states is given exclusively by the interaction of the muonic atom with the magnetic field. However due to its compactness the muonic helium has considerable relativistic corrections which could in principle suppress the above-calculated transition rates. The measured \( 2s_1/2 - 2p_3/2 \) splitting is \( \Delta E_{2S-2P} = 1.527 eV \) \([22]\). The main contribution in the \( \Delta E_{2S-2P} \) splitting is given by the vacuum polarization (VP) effect \( \Delta E_{VP}^S\perp = 1.667 eV \) \([24]\), which is dominant among other relativistic and short-range corrections in the muonic helium \([24]\). Muonic ions (atoms) are much more sensitive than electronic ones to the VP alteration of the Coulomb interaction, because the dimension of the muonic ion \( a_0/z = \hbar^2/(m_\mu e^2 z) \approx 2.6/z \cdot 10^{-11} cm \) is close to the Compton electron wavelength \( \lambda_e = \hbar/m_e c \approx 3.9 \cdot 10^{-11} cm \).

To evaluate the influence of the main relativistic effect on the magnetic field stimulated \( 2s - 2p \) transitions we have integrated the Eqs.(6)-(10) with the additional VP potential

\[
\Delta U(r) = - \alpha \frac{2z}{3\pi} \int_1^\infty \frac{\sqrt{x^2 - 1}}{x^2} (1 + \frac{1}{2x^2}) e^{-2(r/\lambda_e)x} dx,
\]

including in the Hamiltonian \((7)\) an effective interaction between the muon and helium nucleus due to the virtual production of a single \( e^+e^- \) pair. The results presented in Fig.3 demonstrate that the slowing down of the 2s state depopulation due to the relativistic \( 2s - 2p \) splitting becomes considerable for times of the order \( t \approx 10^{-10} s \) for the chosen parameters of \( B \) and \( v_\perp \).

The calculated rates of the \( 2s - 2p \) and \( 3s - 3p - 3d \) mixing exceed, at least by two order of magnitude, the rates of the resonance muonic molecule formation \((\sim 10^8 - 10^9 s^{-1})\)\([1-4]\) and are comparable with other transition rates of the \( \mu He^+ \) in the process of the deceleration in a dense deuterium-tritium mixture (transitions due to inelastic collisions, Auger transitions, Stark mixing \([18, 23, 26]\)). Transitions between different \( n \), stimulated by the driven field of the order of a few Teslas, are much slower then sub-level transitions with the same \( n \). Thus, for low density with suppression of the collisional transitions such that only the radiative transitions \( nl \to n'l' \) between some known states are remained essential \([18, 19]\), one can drive the sub-levels population \( P_{nl} \) by varying the strength of the applied magnetic field. Different modelling of the \( \mu He^+ \) ion time-evolution in \( dt \) mixture show the strong dependence of the muonic ions \( x\)-ray yield from the \( 2s - 2p \) population (especially for \( K_\alpha \) radiation). Some estimations show also an influence of these populations on the reactivation rate \( R \) \([18, 23, 27]\). Both parameters, reactivation rate \( R \) and \( K_\alpha \) lines intensity, are under extensive experimental investigation so far \([21, 24, 28]\). Thus, the experimental achievement in \( \mu CF \) makes it possible to analyze directly the influence of the driving magnetic field to the \( K_\alpha \) \( x\)-ray production and the reactivation rates \( R \) by measuring these parameters at low densities in the presence of external magnetic fields. The possibility to create a well-defined mixing of the \( l \) sub-levels in such kind of experiments looks especially valuable, because different hypothesis about the \( 2s - 2p \) mixing have been used so far in modelling the \( \mu He^+ \) time-evolution \([18, 19]\) due to a considerable variation for the estimates of the \( 2s - 2p \) Stark mixing by different authors \([19, 25-27]\).

IV. SELF-IONIZATION OF HIGHLY EXCITED FAST MUONIC HELIUM IONS IN STRONG MAGNETIC FIELDS

In refs. \([14]\) the self-ionization process for ions in the presence of an external magnetic field has been predicted and demonstrated by solving the classical equations of motion for Rydberg states of the one-electron \( He^+ \) ion. Here we discuss briefly the possibility to ionize the fast highly-excited \( \mu He^+ \) ion by a strong magnetic field. Actually, the
muon kinetic energy in the direction of the magnetic field $\mathbf{B}$ can become large enough in order to ionize the system through the energy transfer from the CM to the internal motion according to Eq.(14). Perpendicular to the magnetic field the muonic motion is finite because of the confining property of the magnetic field. This is a principal difference of the self-ionization in the presence of a magnetic field compared to the classical ionization by an external electric field.

In the present calculations (the initial population is chosen to be $P_{15s}(t=0) = 1$, i.e. the $n = 15, l = m = 0$ state) we used a more detailed grid over $r \in [0, r_m = 1500a_0]$ (400 grid points) as compared to the calculations for the low-lying states $n = 2, 3$. The boundary $r_m$ was chosen approximately 10 times exceeding the initial value of the mean radius ($r$) of the $\mu He^+$ ion in the $n = 15, l = m = 0$ state. Following the Refs. [13,29] we have used an absorbing boundary condition at the point $r = r_m$. It permits to prevent the artificial reflection of the muon flux from the grid boundary as well as allows an estimation of the ionization rate by analyzing the decay of the muon norm $N_{15s}(t) = \int |\psi(r, t)|^2 \, dr$ with time [24].

The calculated time-evolution of the muon densities in $z$-direction of $\mathbf{B}$ and the perpendicular direction are presented in Figs.4 for the strong field $B = 4 \cdot 10^3$ Tesla. They demonstrate considerable spreading of the muon density in $z$-direction for $t \geq 2 \cdot 10^{-11}$s. The evaluated norm $N_{15s}(t)$ (Fig.5) gives the following estimate $t_I \simeq 10^{-10}$s for the order of the self-ionization time. This shows that the self-ionization is at least one order of magnitude faster than the process of the muonic molecule resonant formation ($\sim 10^{-8} - 10^{-9}$s[1-4]) and potentially may be useful for increasing the muon stripping from the highly-excited states ($n \sim 15$) of the ($\mu He^+$)$_n$ ions. However, it is at the time being not clear how to make this process efficient with respect to the increase of the reactivation rate $R$. Actually, the ($\mu He^+$)$_n$ ions are formed in reaction (11) mainly in low-lying excited states (only a few percents of the muonic ions are in $n > 5[1-4]$) for which the self-ionization is much slower. Our estimates, made for the same field strength $B = 4 \cdot 10^3$ Tesla show a fast increase of the self-ionization time with decreasing $n$. Particularly, for $n = 5$ the self-ionization time already exceeds the critical value $\sim 10^{-8}$s defined by the resonant muonic molecule formation. In principle it may be compensated by increasing the strength of the applied field to $B > 4 \cdot 10^3$ Tesla, which is, however, orders of magnitude beyond the currently available fields at high magnetic field facilities [30]. The so far known mechanisms [27] also do not permit an efficient excitation of the fast muonic ions.

V. CONCLUSIONS

In this work we analyzed the transitions stimulated by external magnetic fields from excited states of the fast $\mu He^+$ ions. The results have been obtained within an approach developed for treating non-adiabatic two-body charged system in external magnetic fields on a mixed quantum-semiclassical level.

It was shown that the present-day laboratory fields of the order of a few Tesla may stimulate strong $2s - 2p$ mixing as well as $l$ mixing of the sub-levels for $n > 2$ in the $\mu He^+$ ions forming in $\mu CF$. The effect of the magnetic field stimulating the $2s - 2p$ transitions can be analyzed experimentally by measuring the dependence of the intensities of the $K\alpha$-lines from the $\mu He^+$ on the field strength. It is also interesting to analyze experimentally the influence of this effect on another important $\mu CF$ parameter, the reactivation rate $R$, due to the possible dependence of the value $R$ on the $2s - 2p$ mixing in $\mu He^+$ [23,24].

The possibility of the self-ionization process for fast $\mu He^+$ ions in highly excited states has been demonstrated for strong magnetic fields.
