**Abstract.** The mechanical properties of the CsH$_2$PO$_4$ and hybrid compounds with different polymers (SKF-26, UPTFE, Butvar B-98) was determined by the Vickers microhardness test for the first time. It was shown that increase in the volume fraction of the polymer results in the low HV values corresponding to the high robustness of the membranes to plastic deformation. Mechanical properties of hybrid compounds depend on polymer type and the best results were obtained for SKF-26. The improvement of mechanical properties makes the investigated composite polymer electrolytes promising for use as proton-conducting membranes in the medium-temperature range.

1 Introduction

The growing interest in high proton-conducting materials in the medium temperature range of 200-400°C is associated with their use in various electrochemical devices, including fuel cells (FCs). Electrolytes for FC application must have several required characteristics such as high proton conductivity, low electronic conductivity, low gas permeability, mechanical strength, and high chemical stability. The CsH$_2$PO$_4$ based membranes undoubtedly have great potential for application for a medium-temperature FCs due to the existence of the superionic cubic Pm-3m phase with high values of conductivity ($6 \cdot 10^{-2}$ S/cm at $T = 240^\circ$C) [1-3]. Despite its attractive electrochemical characteristics, CsH$_2$PO$_4$ has poor mechanical stability due to the time-dependent plasticity of acid salts in superionic phases [1]. Electrolytes composed of pure CsH$_2$PO$_4$ can be deformed under compressive loading resulting in fuel leaks and voltage losses. Also, creep destroys electrode structure breaking the triple-phase boundary sites and lowering FC performance.

Researches on composite systems based on CsH$_2$PO$_4$ and polymer additives are being intensively developed. Such systems combine the strength, flexibility, and hydrophobicity of a polymer component with a high proton conductivity of an acid salt. Polymer additive makes it possible to obtain thin membranes thus reducing ohmic losses. In most cases, the crystal structure of the salt and its thermal properties were not affected by the polymer, while the proton conductivity decreased in proportion to the amount of the non-conducting

polymer additive due to the «conductor-insulator» percolation effect [1-5]. According to the literature data, the mechanical strength of polymer composite electrolytes was investigated [5, 6]. Mechanical tensile strength for the PVDF membrane demonstrated rather high values of ~ 58 MPa. Composite electrolytes have a significantly lower tensile strength due to the addition of CsH2PO₄ particles. So for a composite electrolyte with 70 wt. % CsH₂PO₄, a tensile strength of 7 MPa was obtained. With an increase in the salt content, a further decrease in the strength characteristics is observed [5] Similar results were obtained for composites based on CsH₂PO₄ with epoxy rubber and SPEEK [1, 6]. Despite the decrease in strength characteristics, the mechanical stability of «CsH₂PO₄-polymer» composite electrolytes significantly exceeds the initial salt. As for the mechanical properties of pure acid salts of the MₓHₙ(AO₆)ₙ family (where M=Cs, Rb, NH₄⁺, A=P, As, S, Se, and m, n, p are integers) there is no detailed information. Mechanical properties of CsHSO₄ and KH₂PO₄ have been investigated [1-3]. For tetragonal KH₂PO₄ single crystal, the value of the large-load Vickers hardness ~1.4 GPa was estimated as the load-independent and orientation insensitive [13]. Along with tensile strength measurements and 3-point flexural testing of the composite membranes, nanoindentation is a perspective method to evaluate the mechanical properties of materials. Vickers hardness test is used to observe the ability of a material to resist plastic deformation from a standard source with a diamond in the form of a square-based pyramid as an indenter.

This work is devoted to the study of the mechanical properties of polymer composite electrolytes based on CsH₂PO₄ by the Vickers method. As a polymer additives copolymer of vinylidenefluoride with hexafluoropropylene (SKF-26), ultradispersed polytetrafluoroethylene (UPTFE Forum®) and polyvinyl butyral (Butvar® B98) were investigated. The studied polymers have a high decomposition temperature (~ 250°C) are chemically stable and are resistant to the action of many aggressive media. Previously the detailed studies of the synthesis method, transport characteristics, structural properties, and morphology of the polymer composite membranes have been carried out [7 - 9].

2 Experimental section

The microindentation test provides a simple way to evaluate the mechanical properties of composite polymer electrolytes. For mechanical properties investigation CsH₂PO₄ powder was uniaxially pressed in a cylindrical compression die for 10 min at a pressure of 300 MPa at room temperature to yield disc specimens of 5 mm in diameter and 1 mm thick. Composites with various polymer content x (wt. %) were obtained by different methods. Composites of the CsH₂PO₄-UPTFE system were obtained by solid-state technique due to the insolubility of UPTFE in common solvents. The appropriate amount of components was mixed and hot-pressed at T=140°C to form a dense tablet. For cesium dihydrogen phosphate, there are no common solvents with SKF-26 and Butvar polymer. The hybrid membranes were obtained by mixing of CsH₂PO₄ salt particles with a polymer solution in a suitable solvent with a mortar and a pestle with a further drying and uniaxial pressing of formed powder at 300 MPa into a dense tablet. The relative density of the obtained tablets «CsH₂PO₄-polymer» was ~ 91-95%.

The Vickers hardness test was performed on Microhardness tester DuraScan 50 (EMCO-TEST, Austria). The indentation load was 0.5 kgf (4.9 N) with an applied time of 10 seconds. Measurements were reproduced at least ten times for each sample. The size of the indentation diagonals on the surface of the membrane after the removal of the load was measured with an optical microscope with a 10-times objective lens. The Vickers Hardness (HV) was obtained automatically by division of the load by the area of the sloping surface of the indentation.
3 Results

The mechanical properties of the initial CsH₂PO₄ salt and hybrid polymer compounds were determined using the Vickers microhardness test. Figure 1 presents the changes of an impression on the surface of membranes of various compositions after the Vickers indentation.

![Images of indenter impressions](image1)

**Fig. 1.** The microscope images of the indenter impression on the membrane surface of the «CsH₂PO₄-polymer» composites with different x.

The microhardness for inorganic salt CsH₂PO₄ was HV~34, which corresponds to 333.4 MPa (Fig. 1a). For a hybrid compound with a SKF-26 polymer content x=0.05 the microhardness is ~19 and reaches HV~10 for x=0.10 (~98.1 MPa). With further growth of polymer content to x≥0.15 there were no visible impressions from the diamond pyramidal indenter (Fig. 1 (b)). For the higher x HV values can’t be obtained because the indentation mark was quickly erased due to the small recovery time of the membranes with high fluoroelastomer content. For the CsH₂PO₄-UPTFE system a similar tendency was observed (Fig. 1 (c)). With x increase, the area of indenter impression increases corresponding to HV values decrease. It confirms that hybrid membranes can resist plastic deformation and their mechanical properties are higher. Besides the high content of fluorine in UPTFE, as well as in SKF-26, makes fluoropolymers promising as a matrix for CsH₂PO₄ due to stability in aggressive media, prolonged heating to high temperatures, and hydrophobicity.

Vickers microhardness of «CsH₂PO₄-polymer» systems depending on the volume fraction of polymer is presented in Fig. 2. Among all the systems studied, fluoroelastomer SKF-26 has the strongest effect on the mechanical properties of the membranes. For x=0.15 that corresponds to ~24 vol. % there was no visible indenter impression. This result exceeds the values for the CsH₂PO₄-Butvar system even at higher volume fractions of the Butvar polymer additive, up to 45 vol. %.

4 Conclusions

The mechanical properties of the CsH₂PO₄ acid salt and hybrid polymer compounds with different polymers (SKF-26, UPTFE, Butvar B-98) were determined by the Vickers microhardness test for the first time. For hybrid compounds, it was shown that with an increase in the mass fraction of the polymer the ability to resist plastic deformation and mechanical strength increase, which makes the investigated composite polymer electrolytes promising for use as proton-conducting membranes in the medium-temperature range.
