Abstract
Aim: This study investigates the colonization rate of Akkermansia muciniphila in the gastrointestinal tracts of people living in southern China and applies a modified method for the isolation and subtyping of A. muciniphila strains from faecal samples.
Methods and Results: Fresh faecal samples were collected and bacterial DNA was extracted from these samples for real-time PCR analysis. Strains were separated using a culture-dependent sPCR-directed method and classified using an enterobacterial repetitive intergenic consensus (ERIC-PCR) DNA fingerprinting method. The colonization rate for the sample population from southern China was 51–74%. We isolated 22 strains from human faeces. The results revealed that all strains were identifiable as A. muciniphila with 99–100% identity to the type-strain ATCC BAA-835. ERIC-PCR resulted in grouping of the DNA fingerprints showed that 12 distinct clusters were distinguished with a delineation level of 100%.
Conclusions: Southern China has a high rate of A. muciniphila colonization and over 12 different subtype strains reside in faecal samples.
Significance and Impact of the Study: Akkermansia muciniphila has a beneficial role in human gastrointestinal tract. These studies provide a better understanding of A. muciniphila and details of its colonization in the human gastrointestinal tract.

Introduction
The gastrointestinal (GI) tract is colonized by a complex and diverse microbiota, which consists of approx. 10¹⁴ bacteria. The influence of numerous factors such as geographic location, age, dietary habits and metabolism on physiological variations in the microbiota have been well established (Finegold et al. 1974; Raoult 2012; Thaiss et al. 2014). Furthermore, changes in the composition of gut microbiota have been linked to several diseases, such as obesity (Ley et al. 2006), eczema (Nylund et al. 2013), irritable bowel syndrome (IBS) (Pimentel et al. 2000), Crohn’s disease (Kaaouach et al. 2012), necrotizing enterocolitis (Mai et al. 2011), and type-2 diabetes (Qin et al. 2012). Akkermansia muciniphila, a mucin-degrading bacteria, is a member of the Verrucomicrobia phylum (Derrien et al. 2004). Akkermansia muciniphila-like organisms are universally distributed in the intestines and make up between 1 and 4% of the bacterial population in the colons of Europeans (Collado et al. 2007; Derrien et al. 2008). Diets, race and geographic location can modulate the overall dominant microbiota (De Filippo et al. 2010; Claesson et al. 2011; Yatsunenko et al. 2012). The Chinese diets, race and geographic location varies from Europe, which may be factors leading to the colonization rate and range varying significantly.

Present knowledge suggests that A. muciniphila is important in maintaining a healthy mucus layer in the human gut (Belzer and de Vos 2012). In previous researches, A. muciniphila has been proposed to be a contributor to the maintenance of gut health (Png et al. 2010; Swidsinski et al. 2011; Vigsnaes et al. 2012). In mouse studies, A. muciniphila played a causative role in lowering the body fat index, decreasing adipose tissue...
inflammation, improving glucose homeostasis, decreasing metabolic endotoxaemia, increasing the number of goblet cells, and increasing gut mucin integrity (Everard et al. 2013; Shin et al. 2014; Anhe et al. 2015). Tests in humans have shown *A. muciniphila* is more abundant in the normal glucose tolerance group than in the prediabetes group which suggests that it may be a marker of type-2 diabetes (T2DM) (Zhang et al. 2013). Other research has shown that, in the process of degrading mucin, *A. muciniphila* produces acetate and propionate (Derrien et al. 2004). It is also linked to a protective or anti-inflammatory role (Png et al. 2010). As a probiotic reckoned to have health-promoting effects in humans, the activity of *A. muciniphila* at the surface of mucosa can help to maintain the mucus layer (Belzer and de Vos 2012).

Despite its important role in the human GI tract, only one strain – Muc1 (ATCC BAA-835) – has been purified from human faeces, and that was isolated in 2004 (Derrien et al. 2004). Meta-genomic data suggest that, in addition to *A. muciniphila*, at least eight additional species of the *Akkermansia* genus colonize the human intestine, and even simultaneous colonization by different species can occur (Van den Abbeele et al. 2011). Strains of differing subtypes have not yet been isolated and reported.

Culture-dependent techniques, which are a beneficial way to elucidate the gut bacterial repertoire, can be used only for a limited range of bacteria in the human gut (Eckburg et al. 2005). Improving culture-dependent methods for isolation of *A. muciniphila* isolation from faeces remains a key challenge in microbiology. *Akkermansia muciniphila* is hard to culture from faecal samples because it requires several days to reach a small colony size despite the richness of the nutrient agar plates. Previous attempts to isolate *A. muciniphila* from stool samples have been unsuccessful (Caputo et al. 2015).

Pulse-field electrophoresis (PFGE) is considered the gold-standard method in molecular typing for bacteria such as *Salmonella*, but it is time-consuming and labour-intensive (Winokur 2003). Many alternative typing methods are also available, such as PCR-based random amplification of polymorphic DNA (RAPD), repetitive extragenic palindromic (REP) methods and ERIC-PCR, which capture variation on a genomic scale, as well as methods for determining specific gene variations (Lim et al. 2005; Torpdahl et al. 2005). ERIC-PCR, which offers high subtyping sensitivity, requires no specific technical expertise and makes use of common laboratory reagents, was chosen as the methodology for this study (Wattiau et al. 2011; Schumann and Pukall 2013). Subtyping bacteria of *A. muciniphila* lays a foundation for subsequent functional analysis and population distribution mapping. However, the detailed subtypes of *A. muciniphila* found in humans still remain unknown.

This study is the first time ERIC-PCR has been used to subtype *A. muciniphila* for further analysis.

In this study, real-time PCR was used to explore the colonization rate in southern China. By using a novel medium-selected sPCR-directed method, some reference strains were isolated from the faecal samples. The ERIC-PCR method was used for further classification.

**Materials and methods**

**New culture-dependent sPCR-directed method**

Preparation of reductive chocolate agar plates (RCP): 10 g peptone, 5 g NaCl, 15 g agar, 0.25 g Na₂S·7H₂O and 800 ml pure water were added to prepare a yeast infusion and the pH was adjusted to 7.2–7.4. The supplied pure water was added to a total volume of 1000 ml. The infusion was autoclaved at 125°C for 15 min. When the temperature had cooled to 70–58°C, we added 100 ml sterile defibrinated sheep blood and vancomycin to a final concentration of 5 μg ml⁻¹. The mix was shaken well in an 80–85°C water bath for 15 min, then mixed thoroughly. About 15 ml liquid medium was poured into each plate. After the plates had cooled and the medium solidified, they were stored at 4°C until use.

High bacterial count faecal samples, as identified by real-time PCR results (Cₚ ≤ 30), were collected and the bacteria isolated for culturing. The liquid mucin medium and mucin agar plates were prepared, and the isolation methods described by Derrien et al. (2004) were followed. Each step was confirmed by PCR using AM1 and AM2 PCR primers. Bacteria were inoculated on mucin agar plates and culture purified on RCP until pure cultures were obtained.

**Real-time PCR for Akkermansia muciniphila**

Fresh faecal samples from 172 healthy people were collected. Total DNA was extracted by using a QIAamp fast DNA Stool Mini Kit (Qiagen, Hiden, Germany), following the manufacturer’s instructions. Two primers were used for the variable regions of the 16s rRNA gene sequence of *A. muciniphila* bacteria (Collado et al. 2007). The primers were:

- AM1, 5’CAG CAC GTG AAC GTG GGG AC 3’
- AM2, 5’CCT TGC GGT TGG CTT CAG AT 3’

A standard curve of Muc1 (ATCC BAA-835T, CIP 107961T) was built using SYBR®Select Master Mix (Cat No. 44729, Life Technologies, Carlshbad, CA) following the manufacturing’s protocol in an ABI Viia7 real-time PCR System (Applied Biosystems, Carlsbad, CA). The procedure included pre-denaturation of DNA samples at 95°C for 2 min (first stage) followed by the amplification
of the denatured DNA samples with 40 cycles at 95°C for 15 s, at 60°C for 30 s, 72°C for 60 s and a final extension at 72°C for 5 min. The fluorescent product was detected in the last step of each cycle. To distinguish the target PCR product from nontarget product, melting curve analysis was performed after amplification using the default settings of the ABI software (Applied Biosystems, Carlsbad, CA) from 60°C to 95°C.

**General PCR**

Two specific primers (AM1, AM2) and bacterial 16s RNA universal primers (1492R, 27F) were used for PCR. General PCR was performed using Takara Taq™ ver. 2.0 (Takara, Dalian, China) according to the manufacturer's instructions. The procedures using primers AM1 and AM2 were done by pre-denaturation of DNA samples at 94°C for 2 min (first stage) and amplification of the denatured DNA samples with 40 cycles at 94°C for 30 s, 60°C for 30 s, 72°C for 30 s and a final extension at 72°C for 7 min. Universal primer (1492R: GGTACCTTGT TACGACIT, 27F: AGAGTTTGATCCTGGCTCA) amplification was done by pre-denaturation of DNA samples at 94°C for 2 min (first stage) and the amplification for 40 cycles at 94°C for 30 s, 50°C for 60 s, 72°C for 120 s, and a final extension at 72°C for 7 min.

**ERIC-PCR**

Primers ERIC-15′ATG TAA GCT CCT GGG GAT TCA C-3′ and ERIC-2 (5′-AAG TAA GTG ACT GGG GTG AGC G3′) were used for ERIC-PCR in the present study. Amplification was done by pre-denaturation of DNA samples at 94°C for 2 min (first stage) and amplification of the denatured DNA samples with 40 cycles at 94°C for 60 s, 52°C for 60 s, 68°C for 8 min and a final extension at 65°C for 16 min.

**Gel electrophoresis**

After PCR amplification, 10 μl of each amplified product was mixed with 2 μl of 6× loading buffer, and the mixture was loaded onto a 1% agarose gel stained with ethidium bromide. After electrophoresis, photographs were taken under UV light to record the results.

**Total bacteria counts**

Ten faecal samples per group, taken randomly from five different age ranges, were selected. One gram of the samples was used and suspended in 9 ml of phosphate-buffered saline (pH 7.0). The suspension was vortexed thoroughly, then serially diluted in PBS. The sample was incubated for 30 min with DAPI stain at a final concentration of 10 μg ml⁻¹ before being filtered on prestained (Whatman Black) membrane filters (0.22 μm pore size; Nuclepore Corp, Maidstone, UK). Bacteria were counted immediately under 400× magnification with a Leica epifluorescence microscope equipped with a mercury lamp. Bacteria were counted in randomly selected areas until either 20 fields or a total of 400 bacteria were counted. Finally, we converted the numerical values into the total number of bacteria per gram using dilution multiples.

**Extraction of genomic DNA**

The bacteria were grown overnight in BHI broth at 37°C. DNA was extracted from 5 ml of cultures using the Ampure Microbial DNA Kit (Magen, Guangzhou China). DNA samples in IRB2 buffer were stored at −20°C.

**Construction of dendrogram and phylogenetic tree**

Scores of ‘0’ and ‘1’ were attributed to the absence or the presence of a band, respectively, for each DNA fingerprint harvested from ERIC-PCR for further analysis. NTYSYPC 2.02 software (Exeter Software, East Setauket, NY) was used to calculate the un-weighted pair group method arithmetic mean (UPGMA) and this was used to construct a dendrogram for cluster analysis of the 22 total strains. A phylogenetic tree was built with MEGA 5.1 (Tamura et al. 2011) using the maximum likelihood method.

**Statistical analysis**

Data were expressed as medians, with interquartile ranges in parentheses. The Mann–Whitney U-test was used to determine the source of significant differences. P < 0.05 indicated statistical significance.

**Results**

**Colonization rate of Akkermansia muciniphila** in southern China

The detailed results of applying real-time PCR to 172 human faecal samples from five age groups are shown in Table 1. The highest colonization rate among the different age groups was in those older than 60, at 69-23%. Total bacteria counts using the DAPI stain method were extrapolated to estimate A. muciniphila as a percentage of overall bacteria. All data are given in Fig. 1 and Table 1.

The colonization rate among male subjects was 53 out of 101 (52-48%) with actual levels ranging from 3·18 to 6·25 log (cells) g⁻¹, while in female subjects 36 out of 71 (50-70%) were colonized with A. muciniphila at levels of...
Table 1 Colonization rate of Akkermansia muciniphila in southern China

| Age (years) | Female | Male |
|-------------|--------|------|
|             | Colonization rate (%) | Log (A. muciniphila cells) g⁻¹ faeces | Colonization rate (%) | Log (A. muciniphila cells) g⁻¹ faeces | Average colonization rate (%) | Log (A. muciniphila cells) g⁻¹ faeces | Proportion of total bacteria (x 10⁻⁵) | Log (total bacteria) g⁻¹ of faeces |
| <1          | 5/10 (50.00) | 3.04 (2.64–5.6) | 8/20 (40.00) | 3.36 (2.96–4.72) | 13/30 (43.33) | 3.21 (2.89–4.72)* | 1 : 11.7 | 9.14 (8.47–10.92) |
| 1–10        | 6/12 (50.00) | 5.60 (3.18–7.01) | 10/20 (50.00) | 5.75 (3.97–7.03) | 16/30 (53.33) | 5.76 (3.72–7.02)† | 1 : 2.75 | 10.32 (9.46–10.91) |
| 10–30       | 4/12 (33.33) | 5.09 (4.77–5.78) | 7/12 (58.33) | 3.26 (3.12–4.99) | 11/30 (36.67) | 4.50 (3.18–5.73) | 1 : 7.24 | 10.64 (10.35–10.93) |
| 30–60       | 12/22 (54.55) | 3.68 (3.25–5.03) | 12/19 (63.16) | 3.42 (3.01–4.71) | 22/41 (53.66) | 3.58 (3.11–5.23) | 1 : 1.17 | 10.51 (10.16–10.76) |
| >60         | 11/15 (73.33) | 5.30 (4.36–6.81) | 16/24 (66.67) | 5.88 (3.45–7.46) | 27/39 (69.23) | 5.58 (3.68–7.23)‡ | 1 : 1.05 | 10.56 (9.72–10.96) |
| Total       | 36/71 (50.70) | 4.89 (3.22–6.57) | 53/101 (52.48) | 4.25 (3.18–6.25) | 89/172 (51.74) | 4.50 (3.18–6.32) | 1 : 11.7 | 10.36 (9.67–10.79) |

Due to non-normal distribution, microbial data were expressed as median, with interquartile ranges in parentheses.

*Control group.
†Significant differences between under 1 year faecal samples and older than 60 years faecal samples (P < 0.05) according to the Mann-Whitney U-test.
‡Significant differences between under 1 year faecal samples and older than 60 years faecal samples (P < 0.01) according to the Mann-Whitney U-test.
16sRNA gene sequences of 22 strains were compiled and a phylogenetic tree showing the position of all 22 strains was created, using the maximum likelihood method, and is shown in Fig. S3. The relationships between \textit{A. muciniphila} subtypes and human health are at present unknown and warrant further investigation.

**Discussion**

\textit{Akkermansia muciniphila} colonization rates in southern China were found to be lower than in European populations (51-71 vs 74-70%). The highest colonization rates were among the elderly in southern China and in adults in Europe. There was no difference between male and female colonization rates in southern China. The influence of factors such as geographic location, age and dietary habits on physiological variations in the microbiota have been reported previously (Finegold \textit{et al.} 1974; Raoult 2012; Thaiss \textit{et al.} 2014). High-level colonization of up to 39 and 84% of the human gut by the \textit{Verrucomicrobia} phylum has been reported in two patients.

**Table 2** Colonization rates in Europe and southern China

| Age (years) | European (%) | South China (%) |
|-------------|--------------|-----------------|
| <1          | 89/150 (59.33) | 13/30 (43.33)   |
| 1–60        | 54/54 (100)   | 49/103 (47.57)  |
| >60         | 43/45 (95.56) | 27/39 (69.23)   |
| Average     | 186/249 (74.70) | 89/172 (51.74)* |

European colonization rate was adapted from data in the study by Collado \textit{et al.} (2007).

*Significant differences between Europe’s colonization rate and the southern China colonization rate ($P < 0.05$) according to $\chi^2$ test.

**Table 3** Detailed information of isolation hosts and 16sRNA sequences BLAST results

| No. | Code name | Sex | Age (years) | Strains (Accession) | 16sRNA sequence identity | Subtype |

\mbox{Journal of Applied Microbiology 120, 452–459 © 2015 The Authors published by John Wiley & Sons Ltd on behalf of Society for Applied Microbiology.}
following broad-spectrum antibiotic treatment, and all reads were assigned to *A. muciniphila* (Dubourg et al. 2013). Studying adult faecal microbiota in a North American cohort, Wu reported that enterotypes are associated with long-term dietary habits (Wu et al. 2011). Diets with low fibre diversity can modulate the overall dominant microbiota, while diets rich in a diversity of plant fibres could promote the diversification of the overall microbiota by promoting diverse, dominant hydrolytic bacteria (De Filippo et al. 2010; Claesson et al. 2011; Yatsunenko et al. 2012). All of the above factors may lie behind this intercontinental diversity in the colonization rate.

Culture-dependent approaches are traditional and essential means for microbial research. These approaches are based on the cultivation of natural isolates that can be screened for activities of interest, such as the action of enzymes, antimicrobial activity or resistance to antibiotics (Vester et al. 2015). However, only a small minority of micro-organisms can be cultured from samples of the intestinal tract. Improving culture-dependent approaches and obtaining new species thereby would greatly enhance the development of microbiology. In order to culture more *A. muciniphila* strains, our team developed the culture-dependent sPCR-directed method to isolate similar strains from different fresh faecal samples based on the method described by Muriel (Derrien et al. 2004). This method saves time in isolation of the bacteria and we successfully isolated 22 strains from Chinese human faecal samples. Studying the complexity of microbial communities in the gut is a challenge, and better isolation methods are required for more conclusive research into the gut microbiome. Improved cultivation should be combined with the new tools of metagenomics.

Faeces samples were selected on the basis of species specific PCR, and 22 strains were isolated from faecal samples. Different people had different subtypes, and three subjects presented multiple subtypes. Meta-genomic data suggested that at least eight different species of the *Akkermansia* genus, apart from *A. muciniphila*, colonize the intestines of humans, and simultaneous colonization by different species can occur (van Passel et al. 2011; Belzer and de Vos 2012). Discrimination of *A. muciniphila* isolates below the species level is very important to understand the detailed composition of the gut microbiome and enable future function analysis. The molecular methods of ERIC-PCR were able to further classify the subtypes present in these samples. This method displayed higher subtyping sensitivity, required no specific technical expertise and made use of common laboratory reagents (Wattiau et al. 2011; Schumann and Pukall 2013). By using ERIC-PCR, some bacterial strains such as *Escherichia coli* and *Salmonella typhosa* can help us locate the source of outbreaks (Hashemi and Baghban-Arani 2015). Our team was the first to try using this method for *A. muciniphila* isolate subtyping. Finally, we identified 12 subtypes with a delineation level of 100% in Chinese subjects. These findings enable us to investigate further the functionality of these strains in the human GI tract.

These data suggest that southern China has a high colonization rate. More than 12 different subtype strains reside in faecal samples. More in-depth investigations are necessary to explain further the relationship between the *A. muciniphila* subtypes and human health.

**Acknowledgements**

We thank Dr. Muriel Derrien for her helpful discussion in *A. muciniphila* isolation. We thank Professor Ning Fu for her constructive proposal in writing this paper. We thank Dawei Liang for his suggestions in data processing. This research is supported partially by Guangzhou Kangze Medical Science and Technology Co. Limited, Guangzhou, Guangdong, China.
Conflict of Interest

There authors declare that no conflicts of interest exist.
