Received: date / Revised version: date

Abstract. Radiation losses in the interaction of superintense circularly polarized laser pulses with high-density plasmas can lead to the generation of strong quasistatic magnetic fields via absorption of the photon angular momentum (so called inverse Faraday effect). To achieve the magnetic field strength of several Giga Gauss laser intensities $\approx 10^{24}$ W/cm\textsuperscript{2} are required which brings the interaction to the border between the classical and the quantum regimes. We improve the classical modeling of the laser interaction with overcritical plasma in the “hole boring” regime by using a modified radiation friction force accounting for quantum recoil and spectral cut-off at high energies. The results of analytical calculations and three-dimensional particle-in-cell simulations show that, in foreseeable scenarios, the quantum effects may lead to a decrease of the conversion rate of laser radiation into high-energy photons by a factor 2–3. The magnetic field amplitude is suppressed accordingly, and the magnetic field energy – by more than one order in magnitude. This quantum suppression is shown to reach a maximum at a certain value of intensity, and does not grow with the further increase of intensities. The non monotonic behavior of the quantum suppression factor results from the joint effect of the longitudinal plasma acceleration and the radiation reaction force. The predicted features could serve as a suitable diagnostic for radiation friction theories.

1 Introduction

The next generation of high power laser systems \cite{123456789101112} will lead to a new regime of laser-plasma interactions where the emission of incoherent radiation in the X- and $\gamma$-ray range plays a dominant role in the plasma energetics (see e.g. \cite{1315} for review). The modeling of these conditions requires the essential inclusion of radiation friction (RF) effects, i.e. to account self-consistently for the effect of radiation emission on the electron dynamics. In the classical context, RF is accounted for by introducing an additional term to the Lorentz force, acting effectively as friction whose work equals the energy lost into radiation. The expression for the classical RF force has been the subject of a longstanding controversy and several different forms have been proposed. However, it now appears that the expression proposed by Landau and Lifshitz \cite{16} is accurate enough as far as one can neglect quantum effects. The latter become important when the individual energy and momentum of the emitted photons are not small with respect to the energy and momentum of the emitting electron. Although in principle an exact description of the self-consistent interaction of an electron with a strong electromagnetic field may be provided by quantum electrodynamics (QED), in practice such description is technically unfeasible and approximate models are needed.

Recent experiments based on Thomson scattering of a superintense laser pulse by a high-energy electron bunch \cite{171819} have provided a first (albeit weak) evidence for deviations from classical predictions in the radiation spectrum. In the modeling of the experiments, a so-called “semiclassical” approach based on a modification of the Landau-Lifshitz RF force \cite{20} appeared to provide a better agreement than a “quantum” approach where the radiation emission is
the onset of quantum effects is important in order to improve the theoretical and numerical modeling. This scenario suggests that identifying different RF signatures and test their sensitivity to quantum model [22,23,24]. This implies that the axial magnetic field remains of the same order of magnitude but its exact value appears quite sensitive to the quantum modification of the RF force.

In this paper, we include quantum effects in our theory and simulations using a semiclassical approach based on the modification of the RF force via the factor introduced by Ritus [30,31], as was done in the interpretation of experiments [18] and in other recent theoretical works [20,32]. We find that quantum effects lead to a considerable reduction both in \( \eta_{rad} \) and in the magnetic field amplitude. The suppression factor in the value of the conversion efficiency is found to have a minimum SF \( \approx 1/2 \) at intensity \( \approx 10^{24} \) W/cm\(^2\) indicating the existence of an extended intensity domain where the quantum effects make a qualitatively considerable impact, which however does not grow with intensity because of the interplay of two opposite tendencies. This implies that the axial magnetic field remains the same order of magnitude but its exact value appears quite sensitive to the quantum modification of the RF force.

The paper is organized as follows. In the section 2 we give a brief summary of the IFE theory in ultra relativistic laser plasma as considered in Refs. [25,26]. In Section 3 the semiclassical modification of the emission spectrum is explained and the analytic model of [26] is modified accordingly. Section 4 presents results of PIC simulations where the quantum suppression of the RF force is introduced within the same approach as in the model of Section 3. The last section contains summary and outlook.

2 Selfconsistent theory of inverse Faraday effect in the classical regime of interaction

Based on the equations of macroscopic electrodynamics and conservation laws, a description of IFE in the field of an intense laser pulse [25] predicts the maximal amplitude of the quasistatic longitudinal magnetic field excited on the axis of a laser beam to be proportional to the laser magnetic field amplitude \( B_L \) and to the fraction of the laser energy \( \eta \) associated with the irreversible transfer of angular momentum from the laser field to the plasma:

\[
B_{xm} = C \eta a_0 B_0 \equiv C \eta B_L .
\]  

(1)

Here

\[
a_0 = \frac{eE_L}{mc\omega} = \frac{E_L}{B_0}, \quad B_0 = \frac{mc\omega}{e} = 1.34 \cdot 10^8 \text{G}
\]  

(2)

are the dimensionless laser field amplitude and the characteristic magnetic field corresponding to it, respectively. In the classical regime of interaction, the value of \( B_0 \) in (2) corresponds to the wavelength \( \lambda = 2\pi/\omega \approx 800 \text{nm} \) of a Ti:Sa laser. A dimensionless coefficient \( C \) is determined by the shape of the laser pulse and has typical values \( C \approx 0.1 \div 0.2 \). The structure of Eq. (1) is consistent with the general theory of IFE [33,34]. The factor \( \eta \) is defined as

\[
\eta = \frac{\omega L_{obs}}{U_L},
\]  

(3)

where the laser frequency; the value of \( B_0 \) in (2) corresponds to the wavelength \( \lambda = 2\pi/\omega \approx 800 \text{nm} \) of a Ti:Sa laser. A dimensionless coefficient \( C \) is determined by the shape of the laser pulse and has typical values \( C \approx 0.1 \div 0.2 \). The structure of Eq. (1) is consistent with the general theory of IFE [33,34]. The factor \( \eta \) is defined as

\[
\eta = \frac{\omega L_{obs}}{U_L},
\]  

(3)
where \( L_{\text{abs}} \) is the angular momentum absorbed by the plasma and
\[
U_L = A \lambda^3 n_e^2 B_0^2
\]
is the energy stored in the laser pulse of wavelength \( \lambda \). The dimensionless coefficient \( A \) is determined by the pulse focusing and time envelope. Equations (1)–(3) are insensitive to a physical mechanism of the angular momentum transfer. In particular, Eq. (1) applies independently on the impact of quantum effects on the plasma dynamics.

In the high-field regime, radiation of plasma electrons is the only mechanism for energy dissipation, so that \( \omega L_{\text{abs}} = U_{\text{rad}} \), where \( U_{\text{rad}} \) is the energy radiated out by the electrons \([25]\), and Eq. (3) reads
\[
\eta \equiv \frac{\eta_{\text{rad}}}{U_{\text{L}}} = \frac{U_{\text{rad}}}{U_{\text{L}}} = \frac{\int d^3r \int dt P_{\text{rad}}(r, t) n_e(r, t)}{U_{\text{L}}} \leq 1. \tag{5}
\]
Here \( P_{\text{rad}} \) is the emission power for a single electron moving under the action of the local electromagnetic field which includes also that created by the plasma and \( n_e \) is the electron concentration. Small values of the characteristic wavelengths of emitted radiation, \( \lambda \approx \lambda_L / a_0^2 \approx 10^{-8} \div 10^{-8} \text{cm} \) guarantee that the emission process is entirely incoherent, so that possible effects of interference are discarded in Eq. (5). In order to proceed with the estimation of \( \eta_{\text{rad}} \) we adopted the following assumptions \([26]\):

(i) plasma electrons radiate independently in the field of a plane CP electromagnetic wave;
(ii) the laser field attenuation inside the plasma and the time-space distribution of the laser energy are accounted for while calculating the integral in Eq. (5);
(iii) effect of the RF force on the electron motion is taken into account selfconsistently using the Zeldovich model for a CP electromagnetic wave propagating through a homogeneous plasma \([27]\);
(iv) the global motion of the plasma slab is accounted for within the “hole boring” model \([28, 29]\);
(v) effect of quantum recoil on motion and radiation of electrons is discarded.

Despite of simplifications (i)–(iv), the analytic model of \([26]\) reproduces results of 3D PIC simulations with a 20% accuracy\(^1\) and shows that longitudinal acceleration of the plasma and attenuation of the laser field on a small evanescence length inside the plasma, together with effects of time-space averaging, lead to a considerable suppression in the conversion efficiency \( \eta_{\text{rad}} \), Eq. (5), so that, ultimately it does not exceed \( \eta_{\text{rad}} \approx 0.2 \) for \( a_0 = 600 \), leading to the upper limit estimate of the magnetic field, Eq. (1), \( B_{\text{cm}} \approx 0.04a_0 B_0 \approx 3.2 \cdot 10^3 \text{G} \) at laser intensities \( I_L \approx 1.7 \cdot 10^{24} \text{W/cm}^2 \).

As far as restriction (v) is concerned, both the model of \([25, 26]\) and the PIC simulation are based on the classical equations of motion for charged particles and classical expressions of the radiation power discarding the effect of quantum recoil on the spectrum of emitted radiation. The parameter \( \chi \)
\[
\chi = \frac{e_0}{m^3 c^2} \sqrt{-(F_{\mu
u} p^\nu)^2} = \frac{E_L'}{E_{\text{cr}}}
\]
which determines the significance of quantum effects and equals to the ratio of the external (laser) electric field in the electron rest frame \( E_L' \) to the critical field of quantum electrodynamics \([33, 34, 37]\), \( E_{\text{cr}} = m^3 c^3 / e_0 c = 1.32 \cdot 10^{16} \text{V/cm} \), remains smaller than unity up to intensities \( I_L \sim 10^{25} \text{W/cm}^2 \) making classical description of dynamics and radiation of electrons applicable at least on the qualitative level. From the other side, the spectrum of emitted photons appears considerably modified by quantum effects already for \( \chi \approx 0.1 \) \([30, 20, 32]\). This is achieved, for the considered parameters, already at \( a_0 \approx 200 \) \( (I_L \approx 1.9 \cdot 10^{23} \text{W/cm}^2) \), so that quantum corrections to the power of radiation may become numerically significant. In the following, we qualitatively probe possible manifestations of the quantum effects in the considered problem at intensities which leave the parameter \( \chi < 1 \).

### 3 Quantum effect on the conversion efficiency

First, we introduce the quantum factor \( g(\chi) \) which describes the suppression of the radiation power due to the off-set in the emission spectrum \([30, 20]\). The classical radiation power for a particle moving along a circle with a transverse velocity \( v_0 \) and drifting in the longitudinal direction with a velocity \( v_z \) is given by
\[
P_{\text{rad}} = \frac{2e^2 \omega^2 \gamma v_0^2}{3c^3} \left( 1 - \frac{v_z}{c} \right)^2 \equiv 2 \frac{\alpha \lambda^2 m^2 c^4}{\hbar}.
\]
To account for the quantum effect of suppression, this classical equation is replaced by

\[ \tilde{F}_{\text{rad}} = g(\chi)P_{\text{rad}} \cdot \]  

(8)

General formulas for the quantum factor \( g(\chi) \) can be found in [30][20]. For practical calculations we use a fit suggested in [38]:

\[ g(\chi) = \left( 1 + 12\chi + 31\chi^2 + 3.7\chi^3 \right)^{-4/9} . \]

(9)

In the ultrarelativistic limit the RF force is proportional to the radiation power

\[ F_{\text{rad}} = -\frac{P_{\text{rad}}v}{c^2} , \]

(10)

so that the quantum factor enters it in the same way \( F_{\text{rad}} \rightarrow \tilde{F}_{\text{rad}} = g F_{\text{rad}} \). As a result, the equation connecting the gamma-factor \( \gamma \) with the dimensionless field amplitude \( a_0 \) is modified as [39]

\[ a_0^2 = \gamma^2 (1 + g^2(\chi)\xi^2) . \]

(11)

This equation stems from the equilibrium condition for a stationary circular orbit for an electron moving under the action of the Lorentz and the RF forces, cf. Eq. (14) in [26]. The conversion efficiency is then modified accordingly

\[ \eta_{\text{rad}} = g(\chi)\xi^4 \frac{\gamma}{a_0} , \]

(12)

cf. Eq. (16) in [26]. This equation relates to the case of a laser field homogeneous both in the propagation direction and the polarization plane. Note that in Eqs. (11) and (12) the gamma factor \( \gamma \) and the parameter

\[ \xi = \frac{4\pi r_e}{3\lambda} , \text{ with } r_e = \frac{e^2}{mc^2} \]

(13)

are taken in the reference frame co-moving with the slab of radiating electrons. In the following, we will denote this reference frame \( K \) to distinguish it from the laboratory frame \( K_0 \) where the corresponding values are denoted as \( \gamma_0 \) and \( \xi_0 \). The same applies to Eq. (11). Taking into account that a Lorentz transformation does not change the values of electric and magnetic fields along the boost axis, Eq. (1) gives also the magnetic field in the laboratory frame \( K_0 \) although the conversion efficiency, Eq. (12), and the values of \( n \) and \( \gamma \) in the ultrarelativistic limit the RF force is proportional to the radiation power

\[ F_{\text{rad}} = -\frac{P_{\text{rad}}v}{c^2} , \]

(10)

\[ g(\chi) = \left( 1 + 12\chi + 31\chi^2 + 3.7\chi^3 \right)^{-4/9} . \]

(9)

In the ultrarelativistic limit the RF force is proportional to the radiation power

\[ F_{\text{rad}} = -\frac{P_{\text{rad}}v}{c^2} , \]

(10)

so that the quantum factor enters it in the same way \( F_{\text{rad}} \rightarrow \tilde{F}_{\text{rad}} = g F_{\text{rad}} \). As a result, the equation connecting the gamma-factor \( \gamma \) with the dimensionless field amplitude \( a_0 \) is modified as [39]

\[ a_0^2 = \gamma^2 (1 + g^2(\chi)\xi^2) . \]

(11)

This equation stems from the equilibrium condition for a stationary circular orbit for an electron moving under the action of the Lorentz and the RF forces, cf. Eq. (14) in [26]. The conversion efficiency is then modified accordingly

\[ \eta_{\text{rad}} = g(\chi)\xi^4 \frac{\gamma}{a_0} , \]

(12)

cf. Eq. (16) in [26]. This equation relates to the case of a laser field homogeneous both in the propagation direction and the polarization plane. Note that in Eqs. (11) and (12) the gamma factor \( \gamma \) and the parameter

\[ \xi = \frac{4\pi r_e}{3\lambda} , \text{ with } r_e = \frac{e^2}{mc^2} \]

(13)

are taken in the reference frame co-moving with the slab of radiating electrons. In the following, we will denote this reference frame \( K \) to distinguish it from the laboratory frame \( K_0 \) where the corresponding values are denoted as \( \gamma_0 \) and \( \xi_0 \). The same applies to Eq. (11). Taking into account that a Lorentz transformation does not change the values of electric and magnetic fields along the boost axis, Eq. (1) gives also the magnetic field in the laboratory frame \( K_0 \), although the conversion efficiency, Eq. (12), and the values of \( B_0 \), Eq. (2), and \( B_L \) are defined exclusively in \( K \). To connect different values in \( K_0 \) and \( K \), we follow the model of [26] and assume below that the average drift velocity of the electrons is close to that of the ions and given by the hole boring velocity [29]

\[ v_\nu \approx v_{\text{HB}} = c\frac{\sqrt{\Theta}}{1 + \sqrt{\Theta}} , \quad \Theta = \left( \frac{a_0}{a_{\text{HB}}} \right)^2 \]

(14)

with the parameter

\[ a_{\text{HB}} = \sqrt{\frac{A m_0 m_p}{Z n_c m}} \]

(15)

where \( A \) and \( Z \) are the atomic and charge numbers of the ions, \( n_0 \) is the initial electron concentration, \( n_c = m_0 c^2/4\pi e^2 \) is the critical concentration and \( n_0 \) is the proton mass. In the present paper the simulation was performed for \( Z/A = 1/2 \) and \( n_0 = 90n_c = 1.55 \cdot 10^{23} \text{ cm}^{-3} \) (same as in [25][26]), then \( a_{\text{HB}} \approx 6 \cdot 10^2 \). The longitudinal motion becomes significantly relativistic at \( a_0 \approx a_{\text{HB}} \).

Using Zeldovich solution [27] the quantum parameter \( \chi \) can be expressed via the values \( \xi \) and \( \gamma \) in the frame \( K \) as [26]

\[ \chi = \frac{3hc}{2e^2} \xi^2 \approx 2 \cdot 10^2 \xi^2 . \]

(16)

Within this model, the values of \( \gamma \) and, consequently, of \( \eta_{\text{rad}} \) are determined by two parameters \( a_0/a_{\text{HB}} \) and \( a_0/a_{\text{cr}} \) with

\[ a_{\text{cr}} = \xi_0^{-1/3} \approx 400 , \]

(17)

where \( \xi_0 \) is given by Eq. (13) calculated in the frame \( K_0 \) for \( \lambda_0 = 800 \text{nm} \). For a flat-top laser pulse with intensity homogeneously distributed in space and time, the conversion efficiency is given by the ratio of the full radiation power of all the electrons to the laser intensity. A simple calculation (see [26] for details) gives then

\[ \eta_{\text{rad}} = \frac{2\xi g(\chi) a_0^2 f(a_0, \xi, \chi)}{1 + \eta_{\text{HB}}(a_0)/c} , \quad f(a_0, \xi, \chi) = \frac{1}{a_0^2} \int_0^{a_0} \gamma^2(a', \xi, \chi) da' , \]

(18)
where the function \( f \) accounts for the laser field attenuation in the plasma. Finally, the fully consistent definition, Eq. (5), involves the ratio of emitted to laser energy which requires integration of the emission power over time and radial coordinate. This definition applies also for laser pulses with an arbitrary space-time envelope and leads (cf. Eqs. (31), (32) in [26]) to the expression

\[
\eta_{\text{rad}} = \frac{2}{a_0^2} \int_0^\infty \int_0^\infty d\rho d\tau \frac{\xi(\rho, \tau) g(\rho, \tau)/(1 + v_{\text{HB}}(\rho, \tau)/c)}{\int_0^\infty \int_0^\infty d\rho d\tau F^2(\rho, \tau)} a_0 F(\rho, \tau) \frac{\gamma^4(a, \xi, \chi) da}{a}.
\]

(19)

Here \( F(\rho, \tau) \) is the axially symmetric laser pulse space-time envelope defined as

\[
a(r, t) = a_0 F(\rho, \tau)
\]

(20)

with dimensionless radial and time variables \( \rho = (r/r_0)^2, \tau = ct/r_L \) and

\[
\xi(\rho, \tau) = \xi_0 \sqrt{1 - v_{\text{HB}}/c}
\]

(21)

is calculated in the frame \( K \) with the hole boring velocity \( v_{\text{HB}} \) dependent on time and radial coordinate through the value of the laser field amplitude, Eq. (20). The \( \gamma \)-factor under the integral in the numerator depends on \( \xi(a_0) \), Eq. (11), and also on the local value of the dimensionless laser amplitude \( a_0 F(\rho, \tau) \). Note that the quantum factor \( g(\chi) \) enters Eq. (19) not only linearly but also through the factor \( \gamma^4 \) under the integral. Finally, the factor \( 1/(1 + v_{\text{HB}}/c) \) in Eqs. (18) and (19) comes from the Lorentz transformation of the emitted energy into the laboratory frame \( K_0 \).

4 Numerical results

By solving numerically Eq. (11) using Eqs. (9) and (16) for the quantum factor \( g \) and the quantum parameter \( \chi \), correspondingly, the conversion efficiency, Eqs. (18), (19), has been found in the interval of intensities \( 10^{23} \rightarrow 10^{25} \) W/cm\(^2\). Fig. 1 shows the conversion efficiency \( \eta_{\text{rad}} \) calculated in the frame \( K_0 \) with and without the function \( g(\chi) \) accounted for. Note that although for an electron which is in average in rest in the frame \( K \), the solution to Eq. (11) considerably deviates from its low-field, \( a_0 \ll a_0, a_{\text{HB}} \), and the high-field \( a_0 \gg a_0, a_{\text{HB}} \) asymptotics. For the supergaussian pulse \( F(\rho, \tau) = \exp(-\rho^2 - \tau^4) \) as used in [25,26], the low-field asymptotic of \( \eta_{\text{rad}} \), Eq. (19), is given by

\[
\eta_{\text{rad}} \approx 0.20g(\chi)(a_0)\xi_0^2.
\]

(22)

In the opposite, strong-field limit the function \( g(\chi) \) slips out, and \( \eta_{\text{rad}} \) tends to a constant < 1 as it is in the classical case (cf. Eq. (29) in [26]). This limit is however nonphysical within the considered model, as it can only be reached at \( \chi > 1 \) when the electron motion is essentially non-classical, so that a full quantum mechanical treatment is required. Thus in the following we focus on the intensity interval \( a_0 \approx 300 \rightarrow 700 \) where the simple low-field asymptotic, Eq. (22), does not apply while the semiclassical description remains relevant.

We compare predictions of this analytic model to the results of 3D PIC simulations (see also [25,26] for details of the numerical set-up) which describe the interaction of a laser pulse with a plasma of thickness \( D = 15\lambda_0 \), where \( \lambda_0 = 800 \) nm corresponding to a Ti:Sapphire laser and initial density \( n_0 = 90n_c = 1.55 \times 10^{23} \) cm\(^{-3}\). The supergaussian laser pulse with the space-time envelope \( F = \exp(-\rho^2 - \tau^4) \) is introduced via the time-dependent boundary condition at the surfaces of the numerical box in a way that at the waist plane \( x = 0 \) coincident with the initial position of the left boundary of the plasma target:

\[
a(r, x = 0, t) = a_0[y \cos(\omega t) + z \sin(\omega t)]e^{-(r/r_0)^4-(ct/r_L)^4}.
\]

(23)

Here \( r = \sqrt{y^2 + z^2} \), \( r_0 = 3.8\lambda \), \( r_L = 3.0\lambda \) and duration (full-width-half-maximum of the intensity profile) 14.6 fs. The numerical box had a \( 40 \times 25 \times 25 \) \( \lambda^3 \) size, with 40 grid cells per \( \lambda \) in each direction and 125 particles per cell for each species. The simulations were performed on 5000 \( \div 10000 \) cores of the JURECA Cluster Module at NIC (Jülich, Germany). The code has been modified by introducing the quantum factor, Eq. (9), in the expression for the radiation...
friction force. To that end the quantum parameter $\chi$, Eq. (6), was calculated at each time step by taking the values of electric and magnetic fields at the position of each macroparticle. The value of $\eta_{rad}$ was found as the ratio

$$\eta_{rad} = \frac{\int dt \int n_e(r,t) \cdot F(r,t) \cdot v(r,t) d^3r}{U_L}$$

with $F$ being the RF force corrected by the factor $g(\chi)$ as described above.

The values of $\eta_{rad}$ extracted from the simulation are shown on Fig. 1b) by triangles and diamonds for the classical and quantum cases, correspondingly. The analytic modeling agrees with the numerical data only qualitatively. To gain a deeper understanding of the quantum effect the conversion efficiency and to provide a more informative comparison between the theory and the PIC results we introduce the suppression factor defined as

$$SF = \frac{\eta_{rad}(\chi)}{\eta_{rad}(\chi = 0)}.$$  

Results shown in Fig. 1 demonstrate the non-monotonic behavior of this factor as calculated from the theory. The same function extracted from the PIC data behaves qualitatively similar with a loosely defined minimum around $a_0 \approx 450$.

Note that the accuracy of the numerical extraction of $\eta_{rad}$ from results of the PIC simulation is close to 1%. This establishes the lower limit of the conversion efficiency which can be reliably found from the data. As a result, the values of $\eta_{rad}$ for $a_0 = 350$ and $g = 1$ and $a_0 = 350$, $400$ and $g = g(\chi)$ bear a $\sim 100\%$ uncertainty. However, the mere fact that $g(\chi) \rightarrow 1$ in the low-intensity limit in combination with a clear growth of the numerically found SF at $a_0 > 500$ makes the existence of the minimum apparent.

To envisage the quantum effect on the generation of extreme magnetic fields via the IFE, we plot on Fig. 2 the distributions of $B_x$ in the plane containing the propagation axis $x$. The comparison is made for the cases when the quantum factor is taken into account, quantum effects are discarded ($g = 1$), but the RF force is accounted for classically (in the same way as in [25,26]) and, finally, the RF force is discarded. It is clearly seen that the quantum effects considerably suppress both the amplitude of the magnetic field and the size of the region where this field exist. For $a_0 = 400$ the ratio of the magnetic field amplitudes $B_{xm}(g \neq 1)/B_{xm}(g = 1) \approx 0.5$ and for $a_0 = 500$ it is close to $0.35$. This results agree qualitatively with Eq. (1) which establishes the linear proportionality of the magnetic field amplitude to the conversion efficiency. The ratio of magnetic energies calculated in the part of the plasma where the longitudinal magnetic field is present appears $0.07$ for both values of intensity present in Fig. 2.

5 Discussion

Our numerical and analytic results show that the effect of quantum recoil suppressing radiation of high-energy photons leads to a considerable reduction in the conversion efficiency and in the maximal value of the magnetic field excited...
via the inverse Faraday effect. The theory predicts the quantum suppression factor to reach the value of \( \approx 0.7 \) already at \( a_0 \approx 250 \). This result looks natural taking into account that in the limit of low intensities the hole boring velocity is small so that \( \xi \approx \xi_0 \) and the RF effect on the electron trajectory is negligible so that \( \gamma \approx a_0 \). Then \( SF \approx g(\chi) \) with \( g(\chi = 0.1) \approx 0.7 \) at \( a_0 = 250 \). The behavior of the suppression factor, Eq. (25), at higher intensities with a minimum at \( a_0 \approx 500 \) looks from the first glance rather counterintuitive. However, qualitatively it agrees with the PIC results which also demonstrate a minimum localized approximately at \( a_0 = 350 - 400 \) followed by a clear growth at higher intensities. The value of this minimum \( SF \approx 0.35 \) is smaller than that predicted by the model.

The very existence of the minimum is not surprising for the applied model which predicts \( \eta_{\text{rad}} = \text{const} \) for \( a_0 \to \infty \). Its actual position and value depend on the values of \( a_{\text{cr}} \) and \( a_{\text{HB}} \). With the increasing intensity the \( \gamma \) factor of electrons grows first linearly with \( a_0 \) and then slower, according to Eq. (11). This leads to the corresponding growth of the quantum parameter according to Eq. (16). At the same time, the hole boring velocity grows almost linearly with \( a_0 \), according to Eq. (14), as long as \( a_0 < a_{\text{HB}} \) which leads to the reduction in the values of \( \xi \) and \( \gamma \) entering Eq. (16). This reduction results in the saturation of the quantum effects in the interval \( a_{\text{cr}} < a_0 < a_{\text{HB}} \). The growth of SF at high intensities is the joint result of the longitudinal acceleration of the plasma and the freezing of the relativistic \( \gamma \)-factor described by the Zeldovich model. This conclusion should not make a wrong impression that the quantum effects disappear at ultrahigh intensities. In fact, at the initial stage of the interaction, before a high value of \( \eta_{\text{HB}} \) can be achieved, the quantum parameter \( \chi \) will reach high values bringing the electron dynamics beyond the classical description.

Fig. 2. Distributions in the longitudinal magnetic field \( B_x/B_0 \) in the \((x,r)\) plane for \( a_0 = 400 \) (left column) and \( a_0 = 500 \) (right column) extracted from PIC simulations without the RF force (a), with the RF force for \( g = 1 \) (b) and \( g\)-factor (9) (c). All distributions are taken at \( t = 32 \cdot 2\pi/\omega \) after the start of the interaction, i.e. when the interaction with the laser pulse is over. The white lines on frames (b) and (c) denote the levels of the magnetic field strength \([-15, -10, -5]\) and \([-7.5, -5, -2.5]\), respectively.
Fig. 3. Distributions in \((x, y)\) plane for the electron density (a), the \(g\)-factor (b) and the radiated power (in arbitrary units) (c) for \(a_0 = 500\) and \(t = 10 \cdot 2\pi/\omega\). Not that although the white regions of the plots formally correspond to \(g \to 0\), their contribution into the radiation power and consequently into the value of \(\eta_{\text{rad}}\) is negligible owing to the negligibly small concentration of electrons there.

Note that emission of high energy photons proceeds predominantly in a very thin plasma layer near the plasma-vacuum border where the laser pulse is being reflected. This is illustrated in Fig. 3 where the plasma density, the value of the \(g\)-factor and the radiation power are shown at a time instant \(t = 10 \cdot 2\pi/\omega\) when the radiation power is close to its maximum. These distributions help to infer the effective value of the \(g\)-factor which appears, for \(a_0 = 500\), on the level \(g \sim 0.3 - 0.7\). Smaller values are also present at the plot, but only in that part of the target where the plasma density is very low and the electron bunches accelerated by the longitudinal field generated due to the charge separation move with a sufficiently large negative \(v_x\). In principle these electrons could make a considerable and even dominant contributions into the radiation power, owing to the factor \((1 - v_x/c)^2 \approx 4\) in Eq. (7). However, the distribution of the radiation power shown in Fig. 3 proves that this is not the case, because of the sufficiently low concentration of such electrons.

In conclusion, we have studied possible effects of the quantum recoil on the generation of ultrahigh magnetic fields through the inverse Faraday effect in a dense plasma irradiated by a short intense circularly polarized infrared laser pulse. The quantum effect was accounted for by the factor \(g(\chi)\) in the radiation power, both in the analytic model and in the PIC simulation, while the electron motion still has been treated classically. This limits our results by intensities \(I_L < 10^{25} \text{ W/cm}^2\) where \(\chi < 1\) in that part of the target which efficiently emits radiation. We show a considerable
suppression both in the conversion efficiency $\eta_{\text{rad}}$ and in the magnetic field amplitude $B_{\text{mrad}}$ and, most importantly, we demonstrate that this suppression is non monotonic with intensity, reaching a maximum at $I_L \simeq 10^{24}$ W/cm$^2$.

Acknowledgment

Authors acknowledge useful discussions on quantum radiation reaction with S. S. Bulanov, A. Di Piazza, A. M. Fedotov and M. Tamburini. The simulations were performed using the computing resources granted by the John von Neumann-Institut für Computing (Research Center Jülich) under the project HRO04.
