Abstract

Landslide dam outburst floods have a significant impact on landform evolution in high mountainous areas. Historic landslide dams on Yigong River, southeastern Tibet, generated two outburst superfloods of \(>10^5\) m\(^3\)/s in 1902 and 2000 AD. One of the slackwater deposits, newly found immediately downstream of historic dams, has been dated to 7 ka BP. One-dimensional backwater stepwise method gives an estimate of 225,000 m\(^3\)/s for the peak flow related to the paleo-stage indicator of 7 ka BP. The recurrence of at least three huge landslide dam impoundments and super-outburst floods at the exit of the Yigong lake during the Holocene greatly changes the morphology of the Yigong river. Recent reports of giant landslides elsewhere on the southeastern Tibetan Plateau indicate repeated landslide dams at the same location, which counters the traditional viewpoint that landslide damming is spatially random, unlike glacial damming that persists at the same location. Repeated landslide damming may be a persistent source of outburst floods as well as impede the upstream migration of river knickpoints in the southeastern margin.

1 Introduction

Large landslide or glacier dams and associated outburst floods have profound impacts on alpine landscape evolution around the Tibetan plateau\(^1\)–\(^5\). The impacts have two side effects. On the one hand, natural long-lived dams as stable knickpoints protect upstream channels from river incision and hence retard headward erosion into the plateau interior. On the other hand, the dammed lake outburst floods may control long-term valley evolution such as erosion of bedrock canyons in the Himalaya. Among them, the so-called superfloods play a key role in bedrock plucking, boulder mobilization, coarse grain comminution that moderate flows have poor competence in\(^6\)–\(^9\). However, superflood events are infrequent and rare direct observations are made. Most information of superflooding process comes from sedimentary records of outburst flood deposits at the downstream of breached dams\(^10,11\). Records of modern and ancient superflood events in a river are useful for verification of the flood geomorphic effects and hydraulic hypothesis.

The Yigong River, a tributary of Yarlung Tsangpo River, southeastern Tibetan Plateau, experienced two well documented modern superfloods of \(>10^5\) m\(^3\)/s in 1902 and 2000 AD\(^12\)–\(^15\) (Fig. 1). Both events were generated by failure of landslide dams at the same location, the Zhamu Creek confluence (Fig. 1B). In this study, we report the findings of old lacustrine and slack water deposits (SWDs) downstream of the Zhamu landslide during the recent field survey (Fig. 1C). Age of the deposits is estimated with radiocarbon and optically stimulated luminescence (OSL) dating methods. We calculate the paleoflood peak discharge related to these deposits by using 1-D step-backwater method and discuss the impact of the three flood events on the Yigong river’s evolution. Such rare direct observations and records of repeated outburst floods at the same river reach are very valuable in verifying paleoflood hydraulic reconstruction and better understanding the role of landslide dam outburst floods in the landscape evolution of the Tibet plateau’s eastern margin.
2 Study Area

The study area is at downstream of Yigong river, a tributary of Parlung Tsangpo which is flow into Yarlung Tsangpo river through the Grant Tsangpo Gorge in the southeastern margin of Tibetan plateau (Fig. 1). It is surrounded by numerous summits > 6000 m a.s.l. in Nyaiqentanglha range on the north and Himalayan range on the south. Local topographic relief is up to 6 km in the gorge between Namche Barwa (7782 m) and Gyala Peri (7294 m) massifs. Warm and humid Indian monsoon reaches further to upstream of Yigong river through the deep gorge. The average annual rainfall descends from ~ 3000 mm at the town of Medog to ~ 1100 mm at the town of Yigong. Abundant precipitation and high relief make it the most active region for monsoonal temperate glaciers with the total area of 2490 km$^2$ in China.

The Yigong region is in highly tectonically active mountain belts where the rock uplift rate is as high as 10 mm/yr. The eastern syntax of Himalaya, a northeast protrusion between India and Asia plates is about 30 km to the south. The Jiali fault, a large WNW-ESE trending strike-slip fault extends from the Yigong to the Parlung Tsangpo, traversing the southeast of the Tibetan Plateau. Due to active tectonic movement and high relief, frequent strong earthquakes happened and triggered numerous geological hazards, e.g. the Great Assam earthquake of 8.6 magnitude in 1950, and the Ms 6.9 Milin earthquake in 2017. The Yarlung Tsangpo suture zone is a distinct boundary of Tibetan source and Himalayan source rocks (Fig. 1A). The Tibetan source block completely contains the study area. Primary outcropped rocks in the area are Proterozoic gneiss, Pre-carboniferous schist, and Carboniferous slate and sandstone. Widespread quaternary deposits including laterofrontal moraines, debris fans, and flood deposits distribute along the river's valley.

The Yigong River has a drainage area of 13,500 km$^2$ and mean annual discharge of 378 m$^3$/s. Two large-magnitude landslides took place in 1902 and 2000 AD at the Zhamu Creek next to the exit of Yigong lake (Fig. 1). Delaney & Evans$^{15}$ reviewed the published literature on the 2000 event and presented a reliable estimate of 115 Mm$^3$ for the landslide volume in 2000. Descriptions of the 1902 event are greatly different because first-hand data are not available and most of records in Chinese literature origin from interviews with local witness in 1960s. Lu et al. $^{16}$ calculated the deposition area of 11.6 km$^2$ and the final deposition volume of 513 Mm$^3$ from a 1:100,000 topographical map that was measured via airborne survey in 1968. Zhou et al. $^{17}$ estimated that the 1902 landslide's volume was 1000 Mm$^3$ (some English literatures report the event emplaced in 1900 ). The failure of the landslide dams produced two documented modern superfloods of $> 10^5$ m$^3$/s in the Yigong river. The floods rushed into the Parlung River at Tongmai junction, traveled into the Tsangpo Gorge on the east flank of the Namche Barwa and Gyala Peri massifs (Fig. 1A). Both of the two landslide dams have not been completely breached and it is argued that the broad Yigong lake was resulted from the 1902 damming$^{15}$.

3 Paleoood Deposits And Peak Flow Reconstruction

3.1 Paleoood deposits
SWDs are fine-grained sediments carried in suspension in high energy floods that are deposited in areas of low velocity, such as embayments, alcoves, and tributary junctions, and are commonly used as paleo-stage indicators (PSIs)\textsuperscript{18,19}. One set of SWDs (N30°8'38.67", E95°0'51.15") was found in the lee of a river bend 8.3 km downstream of the 2000 AD dam near Shuangyu village (Fig. 1C, Fig. 2A). The SWDs underly a 1.4 m thick landslide deposit at 52 m above the river level. The sequence is nearly horizontally bedded and comprises four units (Fig. 2B-C): (i) c. 20 cm thick mixture of coarse sand, fine gravel, and diamicton, possibly reworked; (ii) 160 cm of uniform gray oxidized fine sand; (iii) 70 cm thick silt unit; (iv) 50 cm of coarse sand.

Three charcoal samples were collected from the fine sand unit and one from the coarse sand unit. Radiocarbon ages of the charcoal pieces range from 6.7 ka to 7.1 ka BP by radiocarbon dating at the Beta Analytic laboratory, USA (Table 1). Four samples were also collected for OSL dating at the OSL laboratory of the Institute of Mountain Hazards and Environment, Chinese Academy of Sciences. The OSL dating results are shown in Table 2. Additionally, OSL dating of samples from each of the lower three units was performed on a Lexysg Research automatic TL/OSL instrument at the Institute of Mountain Hazards and Environment, CAS. The sample from the silt unit gave an OSL age of 7.6 ± 0.7 ka, which is consistent with the radiocarbon age. The other two samples gave ages of 18.5 ± 1.7 ka (fine sand) and 15.3 ± 1.4 ka (coarse sand) (Fig. 2D); the difference may be due to their larger grain size, or lack of bleaching in a catastrophic flood event. Combining the OSL and radiocarbon dating results gives a probable age of ~ 7 ka BP for the Shuangyu SWD.

| Sample | Material analyzed | Percent modern carbon | Modern carbon fraction | Age (BP)  |
|--------|-------------------|-----------------------|------------------------|-----------|
| SC1    | Charred material  | 41.73 +/- 0.16        | 0.4173 +/- 0.0016      | 7020 ± 30 |
| SC2    | Organic sediment  | 42.94 +/- 0.16        | 0.4294 +/- 0.0016      | 6790 ± 30 |
| SC3    | Charred material  | 43.10 +/- 0.16        | 0.4310 +/- 0.0016      | 6760 ± 30 |
| SC4    | Charred material  | 42.89 +/- 0.16        | 0.4289 +/- 0.0016      | 6800 ± 30 |

\(^b\) the number of test pieces using Standardised Growth Curve method

In addition, we found lacustrine deposits (N 30°09'05", E 94°59'42") at the mouth of Dayi creek, a Yigong’s tributary, 2 km upstream of the Shuangyu SWDs (Fig. 1C). The 2.2m parallel lacustrine lamination with yellow-brown silt is elevated c. 40.0 m above the adjacent floodplain. It is capped by 4.3 m debris-flow accumulation composed of angular and sub-angular gravels and boulders. A 1.5 m no-bedding mixture with sand and gravels is exposed under the lamination (Fig. 3A). Two pieces of charcoal were taken from the silt deposit and radiocarbon dated at Beta Analytic laboratory, USA (Fig. 3B). The \(^{14}\)C ages are determined as 6.3k Bp and 6.6k Bp, which means the Dayi lacustrine deposits are a little later than the Shuangyu SWD. The sediment sequence is located at the mouth of the branch Dayi creek on the right bank of the Yigong river. The bank is a concave bend behind a narrow reach, where the transport capacity of the 7k Bp superflood decreased and large volume of sediment that carried by the superflood stopped here. We speculate the paleoflood deposits jammed the Dayi’s outlet, forming a small temporary dammed lake in the creek. Inflow silt had deposited in the dammed lake and produced the lacustrine lamination. The upper debris-flow accumulation on the lacustrine deposits implies that it is very likely a large-scale debris flow happened in Dayi and broke out the dammed lake.

### 3.2 The modern flood SWDs

Another SWD was found on the opposite bank of Jiazhong village, a hydraulically sheltered area 3.9 km downstream of the 2000AD breached dam (Fig. 1C). The Jiazhong SWD is located within a cove on the river right bank, and its surface is a grassland about 6.0 m higher than the floodplains on the both banks (Fig. 4A). The excavated section is a 1.2 m thick sequence of fine to medium-grained sand capped by a ~10 cm thick sandy loam at ~21.0 m above the river level. The dark gray fine sand is interbedded with three units of ~10 cm thick grey medium sand and mingled with sub-angular gravels (Fig. 4B). The 0–70
cm upper part is nearly parallel laminated, but the lower part inclines to the river at an angle of ~ 5°, indicating an original local gradient and flow direction. A piece of charcoal collected in the middle of the SWD section was dated at the Beta Analytic laboratory. The measured percent modern carbon is 100.12 ± 0.37 and the radiocarbon age ranges from 1880 to 1956 AD with 87.3% probability. Monsoon seasonal floods of ~ 2100 m$^3$/s peak unlikely reach the location of Jiazhong SWD. The upmost sandy loam is very thin, which means it formed in a relatively short period. Moreover, the SWD’s elevation is close to the 2000AD flood deposits next to it (Fig. 4A). Therefore, we interpret the Jiazhong SWD as the product of the 2000 outburst flood. The Jiazhong SWD’s level can be used as the flood stage indicator of the 2000 event.

3.3 Peak flow reconstruction

The well documented 2000 AD flood can be used as a benchmark to aid reconstruction of historic events. The peak 2000 AD discharge at Tongmai Bridge has been estimated as 126,400 m$^3$/s$^{13}$, 120,000 m$^3$/s$^{12}$, and 124,000 m$^3$/s$^{20}$, with a peak water depth of 52 m. We compare peak discharge calculations for the 2000 AD flood using 15 empirical formulas and know data on breach depth, dam height, volume of released water, and impounded water volume (Table 3)$^{21}$. The MacDonald and Langridge-Monopolis (MLM)$^{22}$ formula produced the closest estimate to the measured discharge, at ~ 130,000 m$^3$/s. So the MLM formula is used to estimate the peak discharge of the 1902 AD event, using data on breach height and released water volume from Delaney and Evans$^{15}$ (Table 4). The resulting discharge of ~ 168,000 m$^3$/s is more than 50 times that of a large monsoon season flood.
Table 3
Estimates of peak discharge for the outburst flood generated by the 2000 AD Yigong dam failure using 15 empirical models listed in Liu et al. 21

| Author                  | Model*                       | Publication date | Peak discharge (m³/s) |

| Webby                   | \( Q_p =0.0443g^{0.5}V_w^{0.365}H_d^{1.4} \) | 1996 | 94314                 |

*Where \( Q_p \) is outburst flood peak discharge, \( V_w \) is the water released (m³), \( V_s \) is barrier lake volume, \( H_w \) is breach depth, and \( H_d \) is dam height. In this study, we only considered complete dam breach, thus, \( V_w \) is the same as \( V_s \) and \( H_w \) is the same as \( H_d \).
Table 4
Basic parameters of the yigong barrier lakes in 1900 AD and 2000 AD

| Year | Water depth (m) | Lake area (km$^2$) | Lake volume* (Gm$^3$) | Peak discharge† (m$^3$/s) |
|------|----------------|-------------------|----------------------|--------------------------|
| 2000 | 55             | 48.93             | 2.015                | 129,944                  |
| 1900 | 73             | 54.08             | 2.838                | 167,943                  |

*Volume was calculated using $V = A^{3.424} \times 3304.5$ (Delaney and Evans, 2015), where $A$ is the area of impounded water

†Peak discharge was calculated using $Q_p = 3.85 \times (H \times V)^{0.41}$ (MacDonald and Langridge-Monopolis, 1984), where $H$ is barrier lake water depth and $V$ is lake volume.

SWD surface elevation is widely used in paleoflood hydraulic reconstruction as a PSI$^{18,23}$. The most commonly used paleoflood peak discharge estimation technique is the 1-D step-backwater method$^{18,24}$. We applied the method to the 2000AD and 7 ka BP events using HEC-RAS 5.0.7 software$^{25}$, assuming a subcritical flow regime. Contour lines interpolated from the ALOS DEM (in 2009 with 12.5×12.5 m spatial resolution) correspond well with channel shape and location in the ETM+ image for 1999, so provide an acceptable record of pre-2000 AD topography. The starting cross section for the step-backwater calculation was set at the Tongmai Bridge bedrock section. A total of 97 cross sections were extracted along the 19.2 km reach with an average spacing of 200 m using the RAS Mapper of HEC-RAS 5.0.7 (Fig. 5A).

Expansion and contraction coefficients of 0.1 and 0.3 were specified, based on channel width. Manning’s n roughness coefficient was calibrated using the peak discharge (126,000 m$^3$/s) and water depth (52 m) of the 2000 AD flood. Computed water surface elevation at the Tongmai and Jiazhong cross sections corresponded well with the 2000 AD flood level when Manning’s $n$ was set as 0.03 and 0.035 for river channel and floodplain, respectively. Sensitivity tests in the model show that a 25% variation in Manning’s $n$ results in a maximum difference of 0.13% in the discharge result. Using these values of the coefficients, a discharge of 225,000 m$^3$/s provides the best approximation for the Shuangyu deposits (Fig. 5B). The calculated values of the velocity and the flow area of the 2000AD flood at Tongmai bridge are 15.7 m/s and 8350 m$^2$, closed to those estimated by Delaney and Evans$^{15}$. For the 7 ka BP flood, the velocity and the flow area at Tongmai bridge are 19.5 m/s and 12360 m$^2$. The paleo-flood with such a magnitude can yield a bed shear stress of 5 kPa, and move large boulders up to 5 ~ 6 m in diameter$^8$.

4 Discussions

The landslide dams and outburst floods greatly changed the landscape of the Yigong river. Delaney and Evans$^{15}$ plotted a speculative pre-existing profile derived from SRTM-3 data. They proposed it could be
the river valley profile before 1900 event (i.e. 1902 event in this paper). The intersect point of the pre-existing channel with the present is about 5.8 km downstream of the breached dam (Fig. 6). The channel slope from the dam to the intersect point is 16.5‰, double of the pre-channel slope. This reach filled up by quick deposits of the landslides and the outburst floods. The sediment supply from the landslides keeps the bed stable under such a steep slope. From the intersect point to the Tongmai bridge, the channel slope is 8‰ which is probably a natural slope without the disturbance of landslide damming.

It is observed that the lake and braided stream system had developed as early as in 1973 from the KeyHole-9 satellite image (Fig. 7A). The lake's level and fluvial deposits show little change even after 23 years (Fig. 7B). We estimate the trapped sediment in the lake is about 0.26 billion m³ with 1 km of the lake's average width. Considering the low sediment concentration of the Yigong river, it should take more than thousand-year span to trap such a huge volume of sediment. It is reasonable concluded that the Yigong lake likely formed as early as 7ka ago and the 1902 landslide accumulation overlapped on the previous residual dam. The height of the dam associated with the 7 ka Bp event was at least 170 m based on the peak discharge of 225,000 m³/s (Fig. 6). The stable knickpoint induces backwater aggradation and protects upstream river channel from incision. We conjecture that the 7 ka Bp dam may be caused by an ancient landslide at Jiazhong village or debris flows in Zhamu or Bailong catchments from the remained site-specific alluvial fan or landslide terrace (Fig. 8).

Glacial and landslide dams in Tibetan-Himalayan rivers contribute greatly to the long-term stability of river knickpoints in the Himalayan syntaxes and, hence, impede incision into the interior of the Tibetan Plateau. Previous research suggests that landslide damming is spatially random, unlike glacial damming repeatedly formed at the same location because of periodic advance of glaciers. However, recent large-scale landslides triggered by earthquakes or ice-rock avalanches at the entrance of the Tsangpo Gorge and on the Parlung River demonstrate that repeated blockage of the rivers by landslide dams at the same location may be common near the eastern syntax of Himalaya. Our findings provide a real case of landslide negative feedback to river incision over geological timescale. The Yigong's three large damming events near Zhamu creek demonstrate that recurrent landslide dammings played a primary role on the stability of some knickpoints when glacial or moraine dams cannot reach to the river trunk.

5 Conclusions

Dammed lake outburst floods are common in the margin of the Tibetan Plateau. In this paper, two slack water and one lacustrine deposits near the 1902 and 2000 AD Yigong landslide dams are reported in detail. From these sediment records, a paleoflood event of ~ 7 ka BP is identified by the radiocarbon and OSL dating tests. The 1-D backwater stepwise method gives a 225,000 m³/s of peak flow for the paleoflood. The peak discharge of the 1902 AD flood is about 168,000 m³/s by comparing 15 empirical models with the 2000 AD flood. The river profile was strongly influenced by the dams and associated outburst floods. It is roughly estimated that a volume of 0.26 billion m³ sediment or even more has been
aggraded upstream of the 2000 AD dam. The slope of the channel immediately after the dam is twice of that before the 7 ka BP event due to rapid settling of the flood sediments. Moreover, at least three superfloods of $>10^5 \text{ m}^3/\text{s}$ happened on the Yigong since 7 ka BP indicate that the recurrence interval of Holocene outburst floods on the southeastern margin of the Tibetan Plateau is much shorter than that of monsoon floods with the same magnitude. The dominant effect of outburst floods should be accounted for in long-term landscape evolution models of the southeastern margin.

| Froehlich                        | \(Q_p = 0.607H_w^{1.24}V_w^{0.295}\)                                  | 1995            | 48528                       |
| Webby                            | \(Q_p = 0.0443g^{0.5}V_w^{0.365}H_d^{1.4}\)                          | 1996            | 94314                       |

*Where \(Q_p\) is outburst flood peak discharge, \(V_w\) is the water released \((m^3)\), \(V_s\) is barrier lake volume, \(H_w\) is breach depth, and \(H_d\) is dam height. In this study, we only considered complete dam breach, thus, \(V_w\) is the same as \(V_s\) and \(H_w\) is the same as \(H_d\).*

Table 4. Basic parameters of the yigong barrier lakes in 1900 ad and 2000 AD

| Year | Water depth (m) | Lake area (km²) | Lake volume (Gm³) | Peak discharge (m³/s) |
|------|----------------|-----------------|-------------------|-----------------------|
| 2000 | 55             | 48.93           | 2.015             | 129,944               |
| 1900 | 73             | 54.08           | 2.838             | 167,943               |
Volume was calculated using (Delaney and Evans, 2015), where A is the area of impounded water.

Peak discharge was calculated using (MacDonald and Langridge-Monopolis, 1984), where H is barrier lake water depth and V is lake volume.

**Figures**

![Figure 1](image1.png)

**Figure 1**

(A) Location of the Yigong river and the Yarlung Tsangpo Gorge. The eastward flowing Yigong River turns southward and flows into the gorge after confluence with the westward flowing Parlung River at Tongmai. The topographic map was extracted from NASA's 90 m Shuttle Radar Topography Mission elevation data. The gray line is the Yarlung Tsangpo suture zone. The yellow lines are the Jiali fault. The black box is the extension of the subfigure B. NB denotes Namche Barwa massif (7782 m), GP denotes Gyala Peri massif (7294 m). (B) Topographic relief of the Yigong's downstream area mapped with the Advanced Land Observing Satellite-1 (ALOS) 12.5 m DEM. The blue and orange outlines denote the ranges of the 1902 AD and 2000 AD landslide dams, respectively. The yellow circles with black crosses denote the location of the sediment records. Tongmai Bridge is in a bedrock reach at the confluence of Yigong and Parlung rivers. (C) ETM+ image from November 15, 2001. The 2000 AD flood greatly changed the river...
channel morphology and local topography. A–A’ marks the location of cross sections in Fig. 2. Note: The designations employed and the presentation of the material on this map do not imply the expression of any opinion whatsoever on the part of Research Square concerning the legal status of any country, territory, city or area or of its authorities, or concerning the delimitation of its frontiers or boundaries. This map has been provided by the authors.

Figure 2

(A) Location of slackwater deposits (SWDs) at Shuangyu Village. Orthographic image taken on May 11, 2020 by Dajiang unmanned aerial vehicle (UAV); (B) Upper part of sedimentary section; (C) Lower part of sedimentary section. Total thickness of section is 2.6 m. SO1 to SO4 denotes luminescence dating sample and SC1 to SC4 denotes radiocarbon dating sample; (D) Cross section and sedimentary sequence
of Shuangyu SWD. The two cross sections derive from UAV survey on May 11, 2020 (solid line) and the Advanced Land Observing Satellite (ALOS) 12.5 DEM (dashed line). Water level is estimated as c. 3 m, based on the mean discharge of 520 m3/s in May. The ALOS DEM is consistent with the UAV survey for the main channel and floodplain, but differs by up to 25 m on river banks and hillslopes.

**Figure 3**

(A). The sediment sequence at the outlet of Dayi creek. (B) Section of the lacustrine deposit between the debris-flow accumulation and the mixture layer. The ruler is 50 cm long.
Figure 4

(A) Location of slackwater deposits (SWDs) on the opposite bank of Jiazhong Village. Orthographic image taken on May 11, 2020 by Dajiang unmanned aerial vehicle (UAV). (B) Exposed sedimentary section of the SWDs. The notebook is 14 cm high.
Figure 5

(A) the locations of 97 cross sections used in HEC-RAS Mapper component of HEC-RAS 5.0.7 for the 1D step-backwater computation from the breached dam to the bridge. (B) Longitudinal profiles of water surface and energy grade elevations calculated using the step-backwater method. Peak discharges of 126,000 m$^3$/s and 225,000 m$^3$/s provided the best approximation for the levels of the SWDs at Jiazhong and Shuangyu.
Figure 6

Profile of the Yigong river downstream and probable water level of the 7 ka BP dammed lake according to a peak flow of 225,000 m$^3$/s

Figure 7

(A) KeyHole-9 satellite image of the Yigong lake on March 26, 1973, and (B) TM satellite image of the Yigong lake on December 27, 1996.
Figure 8

The location of Bailong creek and the ancient landslide at Jiazhong village.
