Male partner antenatal attendance and HIV testing in eastern Uganda: a randomized facility-based intervention trial

Robert Byamugisha¹,5*, Anne N Åstrøm², Grace Ndeezi³, Charles AS Karamagi⁴,5, Thorkild Tylleskär⁵ and James K Tumwine³

Abstract

Background: The objective of the study was to evaluate the effect of a written invitation letter to the spouses of new antenatal clinic attendees on attendance by couples and on male partner acceptance of HIV testing at subsequent antenatal clinic visits.

Methods: The trial was conducted with 1060 new attendees from October 2009 to February 2010 in an antenatal clinic at Mbale Regional Referral Hospital, Mbale District, eastern Uganda. The intervention comprised an invitation letter delivered to the spouses of new antenatal attendees, while the control group received an information letter, a leaflet, concerning antenatal care. The primary outcome measure was the proportion of pregnant women who attended antenatal care with their male partners during a follow-up period of four weeks. Eligible pregnant women were randomly assigned to the intervention or non-intervention groups using a randomization sequence, which was computer generated utilizing a random sequence generator (RANDOM ORG) that employed a simple randomization procedure. Respondents, health workers and research assistants were masked to group assignments.

Results: The trial was completed with 530 women enrolled in each group. Participants were analyzed as originally assigned (intention to treat). For the primary outcome, the percentage of trial participants who attended the antenatal clinic with their partners were 16.2% (86/530) and 14.2% (75/530) in the intervention and non-intervention groups, respectively (OR = 1.2; 95% CI: 0.8, 1.6). For the secondary outcome, most of the 161 male partners attended the antenatal clinic; 82 of 86 (95%) in the intervention group and 68 of 75 (91%) in the non-intervention group were tested for HIV (OR = 2.1; 95% CI: 0.6 to 7.5).

Conclusions: The effect of the intervention and the control on couple antenatal attendance was similar. In addition, the trial demonstrated that a simple intervention, such as a letter to the spouse, could increase couple antenatal clinic attendance by 10%. Significantly, the majority of male partners who attended the antenatal clinic accepted HIV testing. Therefore, to further evaluate this simple and cost-effective intervention method, adequately powered studies are required to assess its effectiveness in increasing partner participation in antenatal clinics and the programme for prevention of mother to child transmission of HIV.

Trial Registration: ClinicalTrials.gov Identifier: NCT01144234.

Background
Approximately 370,000 children were newly infected with HIV during 2009 through mother to child transmission [1]. Sub-Saharan Africa, the region most affected by HIV, accounts for 67% of HIV infections worldwide and 91% of new infections among children [2]. HIV counselling and testing is the access point to HIV prevention, care and treatment programmes. However, access to services for preventing mother to child transmission of HIV in low- and middle-income countries remains limited, with only 26% of pregnant women in such countries receiving HIV tests during 2009 [1].

Following World Health Organization (WHO) recommendations [3], routine antenatal counselling and testing for HIV has been introduced into prevention of mother to child transmission (PMTCT) of HIV programmes in resource-limited settings; this has increased HIV testing rates among antenatal attendees in several sub-Saharan countries [4-10]. Engaging men as partners is a critical component of the PMTCT programme, but their involvement in antenatal care (ANC) and PMTCT services has remained low [11-15]. However, men exercise a huge influence on their wives regarding sexual and reproductive health issues [16,17]. Male involvement in antenatal HIV counselling and testing increases the use of PMTCT interventions in resource-limited settings [18-21] and is associated with reduced mother to child transmission of HIV-1 and reduced infant mortality [22].

In Uganda, HIV is a major public health problem and there was an estimated adult HIV prevalence rate of 6.7% in 2006 [23], yet only 15% of adults know their HIV status. The PMTCT programme was launched in Uganda in 2001 and is currently integrated into mainstream antenatal care services. However, the proportion of male partners of pregnant women tested in antenatal clinics for HIV is low. Further, the proportion of HIV discordance among couples who test is high, ranging from 35% to 50% [23-26]. One objective of the Uganda’s policy change from antenatal voluntary counselling and testing (VCT) to routine antenatal counselling and testing in June 2006 was to increase the proportion of male partners of pregnant women offered HIV counselling and testing services from the PMTCT programme from 3% to 25% by 2010 [27].

A study in Mbale Regional Referral Hospital in Mbale District, eastern Uganda, revealed high antenatal HIV testing rates (more than 90%) among pregnant women [5] as a result of routine antenatal counselling and testing. Nonetheless, antenatal attendance and HIV testing among their male partners remained very low (4.7%) [28] despite the fact that counsellors encouraged the antenatal attendees to invite their male partners for clinic attendance and HIV testing [29]. However, measures to increase male partner participation in PMTCT programmes in Uganda have not been investigated. Therefore, this trial was conducted to evaluate the effect of a written invitation letter delivered to the spouses of women attending their first antenatal visit on couple attendance and partner acceptance of HIV testing at subsequent antenatal clinic appointments within a four-week follow-up period.

Methods
A randomized, parallel group, health facility-based intervention trial was conducted among 1060 new attendees (530 individuals in the intervention group and 530 in the control group) at the antenatal clinic in Mbale Regional Referral Hospital from October 2009 to February 2010. The trial setting has been described elsewhere [29]. Routine HIV counselling and testing were carried out according to the Uganda Ministry of Health guidelines (2006) [27].

A sequential HIV testing algorithm with same-day results, which includes three rapid tests, is carried out using one blood sample: Determine HIV 1/2 assay (Abbott Laboratories, Abbott Park, IL, USA) for first screening; STAT-PAK HIV 1/2 dipstick assay (Chembio Diagnostic Systems Inc.) as a second test; and Uni-Gold Recombigen HIV (Trinity Biotech, Wicklow, Ireland) as a “tie-breaker”. An ANC attendee is classified as uninfected if Determine is negative and as HIV infected if the Determine and STAT-PAK tests are positive. Discordant Determine and STAT-PAK blood samples are further tested using the Uni-Gold test. The HIV test result is reported as positive if the Uni-Gold test is positive and as negative if the STAT-PAK and Uni-Gold tests are negative.

Since 2006, ANC clinic attendees who are HIV-positive undergo CD4 cell counts before being administered appropriate treatments according to the national PMTCT guidelines [27]. The sample size for this trial was calculated using a computer programme, OpenEpi, version 2 (http://www.openepi.com/SampleSize/SSCohort.htm). Based on the assumptions that antenatal couple attendance and HIV testing would increase from 4.5% (without intervention) to 9% (with intervention) with 80% power and 95% confidence intervals, 1060 new antenatal attendees, 530 in each group, were enrolled into the trial. The trial was completed four weeks after enrolment of the last participant.

Eligible trial participants were new attendees, aged 15 years or above, who agreed to attend subsequent antenatal visit(s) within the four-week follow-up period at Mbale Hospital, and were willing to give the invitation and information letters to their male partners.
A male partner was defined in this trial as the male who
impregnated the antenatal attendee in the current preg-
nancy. The exclusion criteria included women who
attended with their spouses at the first antenatal visit or
did not consent to participate in the trial, or had
spouses who were inaccessible.

Women attending without spouses at the first antena-
tal visit were identified at reception in the antenatal
clinic. They were tracked until they had undergone all
the standard clinic procedures (namely registration,
health education, pre- and post-test counselling for HIV,
HIV testing, obstetric examination and treatment). Indi-
viduals were approached by research assistants and
informed about the trial’s objective and the intervention.
Those who agreed to participate in the trial by providing
written consent were enrolled into the trial using an
enrolment form with a randomly generated identifica-
tion number.

Each woman was provided with a letter addressed to
her spouse and given an appointment for a return visit
two weeks later. If the participant was not able to attend
with her partner on the scheduled visit, she was given
another appointment for a return visit two weeks later.
Their identification numbers were marked on their
antenatal cards to aid follow up at the next clinic visit.
The importance of adhering to their ANC visits was
uniformly emphasized. Women who did not return to
the antenatal clinic for their scheduled visits during the
four-week follow-up period were classified as “lost to
follow up”.

At enrolment into the trial by the research assistants,
participants were randomly assigned to two parallel
groups, the intervention and non-intervention groups,
with an allocation ratio of 1:1. The intervention com-
prised an invitation letter addressed to the male partner
of the woman attending her first ANC visit, requesting
him to accompany her on the next ANC visit. The com-
parative arm (non-intervention group) received a letter
containing information concerning services offered in
the antenatal clinic at Mbale Regional Referral Hospital.

Detailed in the invitation letter was the following
information: the appointment date of the woman’s next
antenatal visit; that the antenatal and PMTCT services
are free (no user charges); that these services are ben-
eficial to the couple and their unborn baby, and that their
utilization by men is low; that he was cordially invited
to accompany the woman at her next scheduled antena-
tal visit to discuss important issues concerning her
antenatal care; and that the time spent in hospital
would be minimal.

The information letter, the leaflet, contained details
concerning services provided in the antenatal clinic, and
these included checking the woman’s blood pressure to
detect and manage high blood pressure during

pregnancy. It explained that the woman’s urine is tested
for protein, sugar and infections, that her blood is
checked for low haemoglobin levels, and that her abdo-
men is examined to investigate the wellbeing of the
baby. Lastly, the leaflet informed the woman and her
partner that PMTCT services in the clinic were free of
charge. The letters were of similar length, and content
was comparable, with one being an invitation and the
other being an information leaflet only. Each letter was
duly signed by the principal investigator.

The random allocation list of the identification num-
ers was randomly generated by an independent statisti-
cian from TASO Uganda (The AIDS Support
Organisation). A random sequence generator (computer
programme) at the RANDOM.ORG website [30], which
employed a simple randomization procedure, was uti-
ized. The random numbers were hand-written at the
bottom of the back page of the letters for the interven-
tion and non-intervention groups by the principal inves-
tigator. Each letter was inserted into an opaque
envelope and sealed with adhesive glue to ensure that
participants would not open their husbands’ letters.

The corresponding randomization number was written
on the back of the envelope. No antenatal clinic staff,
co-investigators, research assistants or pregnant women
knew whether the sealed envelopes contained the inter-
vention or non-intervention letters. The randomization
code was kept securely by the principal investigator.
Each woman enrolled into the trial by the research
assistants was given an identification number (serial
number). The appropriate envelope, whose randomiza-
tion number corresponded to the serial number, was
selected and given to the participant to give to her
spouse. The randomization code was revealed to the co-
investigators during data analysis.

Data were collected by five trained research assistants
using a standardized, pre-tested questionnaire, adminis-
tered to participants in English or Lumasaba (local lan-
guage) during exit interviews at subsequent clinic visits
during the four-week follow-up period. Four weeks after
enrolment into the trial, women who had not returned
for their subsequent antenatal visits were deemed to
have been lost to follow up. The research assistants
were knowledgeable in the local language and interview
techniques, and had been trained in terms of the trial
objectives and methods.

The structured interview covered topics concerning
the participant’s education, occupation, religion, ethnic
group, number of pregnancies, household assets, opi-
ions and experiences relating to routine HIV counsel-
ing and HIV testing in the antenatal clinic, and
knowledge of mother to child transmission of HIV and
infant feeding options for HIV-infected mothers.
Furthermore, her partner’s age, occupation and
education was discussed. Participants were asked about partner clinic attendance and partner antenatal HIV testing acceptance. Questionnaires were checked for completeness at the end of each day by the principal investigator and clarification sought from research assistants when queries arose. Data were entered using EpiData version 3.1 [31] by two data entry clerks and were validated by the principal investigator. The data file was exported to PASW Statistics 18 [32] (formerly SPSS) for analysis.

Ethical clearance to conduct the trial was obtained from the Research and Ethics Committee of the School of Medicine, Makerere University, and from the Uganda National Council of Science and Technology. Permission to conduct the trial in the antenatal clinic was obtained from the Mbale Regional Referral Hospital administration through the local institutional review board. Written informed consent was provided by all trial participants. The trial was registered with the ClinicalTrials.gov registry (Identifier: NCT01144234).

The pre-specified primary outcome measure of the trial was the proportion of pregnant women who attended ANC with their partners at the subsequent antenatal visit. The secondary outcome measure was the proportion of men who accepted routine antenatal HIV testing. All participants were included in the analysis for the primary outcome measure in the groups to which they were originally assigned (intention to treat); analysis for the secondary outcome included only participants who attended their scheduled return clinic visits during the follow-up period (per protocol analysis).

The socio-demographic characteristics of the trial participants in the intervention and non-intervention groups were compared using independent sample t-test for continuous variables and the Pearson chi-square test for categorical variables. Correlates of couple ANC attendance (male antenatal clinic attendance) and male partner antenatal HIV-testing in the intervention and non-intervention groups was determined using the Pearson Chi-square test and the independent t-test. Multicollinearity among the independent variables and outliers were investigated. Interactions were explored and binary logistic regression was used to test for confounding variables.

All variables that were significant at the level of p < 0.2 in binary analysis, and the age of participants, were retained in the multivariate regression model. All p values were two-tailed at a significance level of 5%. As indicators of model appropriateness, the goodness-of-fit test (Omnibus Tests of Model Coefficients) of each the final models for male partner antenatal attendance and for partner antenatal HIV-testing in the trial groups was significant (p < 0.05), and the Hosmer and Lemeshow goodness-of-fit test was not significant (p value > 0.05) (see tables 1 and 2).

Results

Trial population and follow up

A total of 1060 new antenatal attendees were enrolled and randomly assigned to the intervention and non-intervention groups (530 women in each group) (Figure 1). Of these, 290 and 310 pregnant women in the intervention and non-intervention groups, respectively, attended the subsequent two antenatal visits as scheduled; response rates were 55% (290/530) for the intervention group and 58% (310/530) for the non-intervention group. No major differences in the socio-demographic characteristics of the trial participants were recorded between the groups (Table 3).

Analysis by intention to treat demonstrated that the proportions of participants who attended with their partners were 16.2% (86/530) and 14.2% (75/530) in the intervention and non-intervention groups, respectively (Odds Ratio, OR = 1.2; 95% Confidence Interval, CI: 0.8 to 1.6) (see Table 4). There was no difference between the intervention and control groups with respect to the main outcome variable using bivariate analysis [Pearson chi-square value (χ²) = 0.35, p-value = 0.55]. The majority of male partners in the intervention group (95%) and non-intervention group (91%), who attended the antenatal clinic with their spouses, accepted HIV testing. There was no statistically significant difference between the intervention and non-intervention groups with respect to male partner antenatal HIV testing using bivariate analysis (OR = 2.1; 95% CI: 0.6 to 7.5) and multivariate analysis (OR = 1.6; 95% CI: 0.4 to 6.8), table 4. The men in the two groups were similar (p-value = 0.39).

The majority of male partners (93%, 150 out of 161) in both trial arms who accepted antenatal HIV counselling and testing were HIV sero-negative. Three men in the intervention group tested positive for HIV (Table 4).

All the female antenatal attendees who participated in the trial accepted antenatal HIV testing. Twenty-five (11 in the intervention group and 14 in the control group) tested positive for HIV (Table 4). Significantly, the male participants of most of these HIV-positive women (84%; 21/25) were not tested for HIV in the antenatal clinic (10 men did not attend the clinic; 11 men attended, but declined to be tested). Of the five couples with known HIV test results, three were discordant: in one couple, the woman was HIV negative and male partner was HIV positive; in two couples, the women were HIV positive and the partners were HIV negative. Two couples were concordant (both partners had HIV-positive test results). Therefore, in this trial, of the 150 couples
who accepted antenatal HIV testing, 2% (three of 150) were identified as HIV sero-discordant.

**Correlates of couple antenatal attendance and male partner antenatal HIV testing**

Using multivariate logistic regression analysis, participants having asked for their partner’s permission to test for HIV was the only variable significantly associated with couple antenatal attendance in the intervention group [adjusted OR (AOR) = 1.9; 95% CI: 1.1 to 3.3] and the comparative group (AOR = 1.8; 95% CI: 1.0 to 3.2) (see Table 1). The likelihood of partner antenatal attendance increased if the partner had completed primary school education (AOR = 1.7; 95% CI: 0.8 to 3.8), but this association was not statistically significant.

The trial demonstrated that the likelihood of male partner HIV testing increased if the participant had asked their partner for permission to test for HIV, and

### Table 1 Correlates of couple antenatal attendance among 600 pregnant women at Mbale Regional Referral Hospital

| Study participants’ characteristics (Variables)a | Male partner antenatal clinic attendance in intervention group (N = 290)b | Male partner antenatal clinic attendance in non-intervention group (N = 310)c |
|-----------------------------------------------|-------------------------------------------------|-------------------------------------------------|
| **Attended** n (%)                           | **Did not attend** n (%)                         | **Unadjusted ORd (95% CI)**                      | **Adjusted OR (95% CI)**                      |
| **Attended** n (%)                           | **Did not attend** n (%)                         | **Unadjusted ORd (95% CI)**                      | **Adjusted OR (95% CI)**                      |
| Age (years)                                  |                                                 |                                                 |                                                 |
| 15-24                                        | 42 (28)                                         | 111 (72)                                        | 1                                              |
| 25 or more                                    | 44 (32)                                         | 93 (68)                                         | 1.3 (0.8-2.1)                                  | 1.2 (0.7-2.1)                                  |
| **Education level**                          |                                                 |                                                 |                                                 |

- Other variables not statistically significant in univariate analysis were: Participant’s place of residence, marital status and total number of pregnancies. Age as a possible confounder and all variables that were significant at the level of p < 0.2 in univariate analysis were retained in the multivariate regression model. Multicollinearity and interaction among the independent variables, and outliers were checked for.
- The goodness-of-fit test (Omnibus tests of Coefficients) of the final logistic regression model in the intervention group was significant [Chi-square statistic ($\chi^2$) = 9.376, degrees of freedom (df) = 3, p = 0.025] and Hosmer and Lemeshow goodness of fit test was not significant [$\chi^2$ = 2.785, df = 6, p = 0.835] as indicators of model appropriateness.
- For the non-intervention group, the goodness-of-fit test (Omnibus tests of Coefficients) of the final logistic regression model was significant [$\chi^2$ = 13.018, df = 6, p = 0.043] and Hosmer and Lemeshow goodness of fit test was not significant [$\chi^2$ = 5.617, df = 8, p = 0.690] as indicators of model appropriateness.

- OR: odds ratio
- CI: confidence interval

*Other variables not significant in univariate analysis were: participant's place of residence, marital status, and total number of pregnancies. Age as a possible confounder and all variables that were significant at the level of p < 0.2 in univariate analysis were retained in the multivariate regression model.

Multicollinearity and interaction among the independent variables, and outliers were checked for.

The goodness-of-fit test (Omnibus tests of Coefficients) of the final logistic regression model in the intervention group was significant [chi-square statistic (χ²) = 11.362, degrees of freedom (df) = 3, p = 0.010] and Hosmer and Lemeshow goodness-of-fit test was not significant [χ² = 3.585, df = 6, p = 0.733] as indicators of model appropriateness.

The goodness-of-fit test (Omnibus tests of Coefficients) of the final logistic regression model in the non-intervention group was significant [χ² = 15.412, df = 6, p = 0.017] and Hosmer and Lemeshow goodness-of-fit test was not significant [χ² = 8.774, df = 8, p = 0.362] as indicators of model appropriateness.

OR: odds ratio
CI: confidence interval
*Statistically significant: p < 0.05 (two-tailed)
**Statistically significant: p < 0.01 (two-tailed)

Discussion

As far as we are aware, this is the second randomized clinical trial to evaluate the effects of a written invitation letter to spouses of antenatal attendees on partner antenatal clinic attendance in sub-Saharan Africa. The effect of the intervention (invitation letter) and the control (information leaflet) on couple antenatal attendance was the case for the intervention (AOR = 2.0; 95% CI: 1.2 to 3.5) and non-intervention groups (AOR = 1.9; 95% CI: 1.0 to 3.6). In addition, the participant being a Christian (AOR = 1.7; 95% CI: 1.0 to 3.0) and their partner being salaried (AOR = 1.8; 95% CI: 1.0 to 3.3) were significantly associated with male partner acceptance of antenatal HIV testing (Table 2).
in the trial was similar. The invitation letter and the information leaflet increased couple attendance at the antenatal clinic from approximately 5% [28] to 16% and 14%, respectively. A simple intervention letter to the spouse could increase couple attendance by 10%. This cost-effective intervention could be implemented in almost all African ANC clinics with PMTCT.

The surprisingly equal effect in both arms of the trial could be because the invitation letter (intervention) and the information letter (control) had an official connotation and were perceived by the male partners to be credible as they originated from hospital. Therefore, these letters influenced male antenatal attendance decisions in similar ways, irrespective of the detailed content.

A recent study, carried out in northern Uganda, has documented that the likelihood of male partner antenatal attendance was increased if men were knowledgeable about antenatal care services and if they obtained health information from health workers [33]. The lack of any significant difference between the intervention and the control letter on couple antenatal attendance could be explained by the low power of the trial as a result of the high loss to follow up of trial participants.

The level of male antenatal attendance in this trial is higher than one carried out in northern Tanzania [11], but lower than those documented in studies from northern Uganda [33], central Kenya [22] and Khayelitsha, South Africa [34]. The age groups of the men in these studies were comparable with those of the male partners.
Table 3 Demographic characteristics of study participants compared between intervention (N = 290) and non-intervention groups (N = 310)

| Characteristics                     | Study groups | P value |
|-------------------------------------|--------------|---------|
|                                     | Intervention n (%) | Non-intervention n (%) |
| Age in years\(^a\)                 |              |         |

| Not salaried                        | 156 (53.8)   | 168 (54.2) | 0.99 |
| Salaried                            | 134 (46.2)   | 142 (45.8) |         |

\(^a\)The median age of the pregnant women was 24 years in both the intervention [interquartile range (IQR): 20-28 years] and non-intervention (IQR: 21-29 years) groups.

\(^b\)The male partners’ median age was 30 years in the intervention group (IQR: 26-38 years) and non-intervention group (IQR: 26-35 years), respectively.

in the current trial. It was also reported in the northern Uganda study that the likelihood of male antenatal attendance was higher if men had attained secondary or higher level education [33], but partner education level was not significantly associated with male antenatal attendance in the current trial. The level of partner attendance in this trial was similar to that reported in a study in Nairobi, Kenya [35].

Significantly, the current trial demonstrated that the majority (more than 90%) of male partners who attended the antenatal clinic accepted HIV counselling and testing for HIV. A similar finding has been reported in other studies in the region [22,35]. The implication of this finding is that increasing male antenatal clinic attendance is vital for involving spouses of antenatal attendees in the PMTCT programme. A woman having sought a partner’s permission for HIV testing was significantly associated with partner antenatal attendance and HIV testing, as demonstrated using multivariate analysis. A similar finding was reported in the Nairobi antenatal clinic study [35]. This suggests that improved communication between couples regarding HIV is an important factor in increasing the number of men accompanying their spouses to antenatal clinics and accessing HIV counselling and testing services.

However, there was a differential effect because the HIV sero-status of approximately 80% of the HIV-positive women’s partners remained unknown, which constitutes a missed opportunity to investigate couple HIV sero-discordance and a failure of the intervention to reach the intended recipients.

The trial demonstrated that at least 2% of the couples were HIV sero-discordant. However, because of the low numbers of male partners tested, this figure is likely to be higher. Other studies in Uganda have reported rates of couples’ HIV sero-discordance at 30% to 50% [23-26]. HIV sero-discordance is a key factor that influences rates of new infections among couples [36], thus increasing the risk of mother to child transmission of HIV during pregnancy, delivery and lactation.

The strength of this trial was the surprisingly comparable effect of a letter - a simple, cheap intervention that was easy to administer - in both arms. It could be argued that the main limitation of this trial was the high loss to follow up rate of approximately 40%, reducing the precision (internal validity) and the power of the trial to detect differences between the effect of the invitation letter and the information letter.

There are several possible reasons for the high rate of loss to follow up. Some pregnant women may have continued receiving antenatal care at lower level health units (health centres) nearest to their place of residence on learning from the midwives on their first antenatal clinic visit that they had low risk pregnancies. Others may not have attended follow-up ANC visits owing to transportation problems as the trial site was a referral hospital. Others could have attended clinics for HIV counselling and testing services and decided to continue with ANC elsewhere.
It is possible that community sensitization activities to encourage men to participate in ANC activities, as carried out in the Khayelitsha trial in South Africa [34], could have helped reduce the loss to follow up in our trial. Being a randomized, health facility-based trial, it is assumed that random allocation of the trial participants to the comparison groups, and masking of research assistants, health staff in the antenatal clinic and the participants, dealt with known and unknown confounders. As one of the health providers in the hospital, the principal investigator (RB) did not directly participate in administering intervention to the trial participants in order to avoid the Hawthorne effect on the internal validity of the trial. The findings of this trial could be generalized country-wide to populations that are similar to the one in the trial area.

Conclusions
The effect of the intervention and the control on couple antenatal attendance was similar in both arms of the trial. In addition, this trial demonstrated that a simple intervention, such as a letter to the spouse, formulated as an invitation or as an information letter, could increase couple attendance by 10%. This intervention could be implemented in almost all African ANC clinics with PMTCT at a modest cost.

The trial also demonstrated that the majority (more than 90%) of the male partners who attended the antenatal clinic accepted HIV counselling and testing for HIV. Therefore, there is a requirement to evaluate this simple, cheap intervention further elsewhere in adequately powered studies to assess its effectiveness in increasing partner participation in antenatal clinics and the prevention of mother to child transmission of HIV. Such studies would better define the trial’s implications for the PMTCT programme.

Acknowledgements
We would like to thank the antenatal attendees and their male partners who participated in the trial, and the research assistants who administered the intervention and collected the data. We would also like to thank the health staff in the antenatal clinic, who facilitated the tracking of the participants in the clinic before the exit interviews.

We conducted the trial as part of the Essential Child Health and Nutrition Project in Uganda, a collaboration between the Department of Paediatrics and Child Health, School of Medicine, Makerere University College of Health Sciences and the Centre for International Health, Bergen University. We received funding for the trial from the Norwegian Council for Higher Education’s Programme for Development Research and Education (NUFU), grant no: NUFU PRO-2007/10119.
