Abstract
Aim: To describe the clinical characteristics and outcomes of adult patients with severe COVID-19, with the exploration of risk factors for mortality in the hospital.

Methods: This study included 20 adult patients diagnosed with COVID-19 admitted to the ICU of DHQ Hospital, Faisalabad (Pakistan). Patients were categorised into the survival group and the death group according to the outcome. We retrieved demographics, clinical manifestations and signs, laboratory indicators, treatment measures and clinical outcomes from the medical record, and summarised the clinical characteristics and outcomes of these patients.

Results: The average age of patients was 70 ± 12 years, of which 40% were male. They were admitted to the ICU 11 days after the onset of symptoms. The most common symptoms on admission were cough (19 cases, 95%), fatigue or myalgia (18 cases, 90%), fever (17 cases, 85%) and dyspnoea (16 cases, 80%). Eleven (55%) patients had underlying diseases, of which hypertension was the most common (11 cases, 55%), followed by cardiovascular disease (4 cases, 20%) and diabetes (3 cases, 15%). Six patients (30%) received invasive mechanical ventilation and continuous renal replacement therapy and eventually died. Acute heart injury was the most common complication (19 cases, 95%). Ten (50%) patients died between 2 and 19 days after admission to the ICU. Compared with dead patients, the average body weight of surviving patients was lower (61.70 ± 2.36 vs 68.60 ± 7.15, \( P = .01 \)), Glasgow Coma Scale score was higher (14.69 ± 0.70 vs 12.70 ± 2.45, \( P = .03 \)), with fewer concurrent shocks (2 vs 10, \( P = .001 \)) and acute respiratory distress syndrome (2 vs 10, \( P = .001 \)).

Conclusion: The mortality rate is high in critically ill patients with COVID-19. Lower Glasgow Coma Scale, higher body weight and decreased lymphocyte count appear to be potential risk factors for the death of patients with COVID-19 in the ICU.

What’s known?
- Mortality rate is higher in critically ill patients with COVID-19 in Japanese, European and American populations.
- Hypertension is the most commonly associated comorbidity in these patients.
INTRODUCTION

On 11 March 2020, because of the alarmingly increasing number of global cases of coronavirus disease 2019 (COVID-19), the World Health Organization declared the outbreak of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) as a pandemic. As of 18 August 2020, the number of globally confirmed COVID-19 cases exceeded 21 million, the number of existing active cases was more than 6 million of which patients with severe COVID-19 accounted for 1% and the mortality rate in 216 countries and regions, based on the cases which had an outcome, was 5%. With the spread of COVID-19 around the world, the intensive care unit (ICU) is one of the major rescue departments for severe pneumonia ensuing from COVID-19. Numerous studies have described preliminary findings of the epidemiology of patients with COVID-19, clinical features, outcomes and risk factors for death. However, there are relatively few studies that have reported clinical characteristics and survival outcomes of critically ill patients with COVID-19. A retrospective study from Italy has published baseline characteristics of patients with COVID-19 admitted to ICU. Similarly, two retrospective studies from Wuhan also described the severe clinical course and outcome of critically ill patients with COVID-19. Another study from Wuhan has reported the poor outcomes in cancer patients infected with COVID-19.

Current research shows that the mortality rate of patients with SARS-CoV-2 pneumonia in the ICU is extremely high, which exerts significant pressure on hospital intensive care resources. More evidence is required to better observe and summarise the characteristics and outcomes of patients with COVID-19 admitted to ICU, which would be essential to guide the treatment of ICU patients and the rational allocation of intensive care resources. This study aimed to describe the demographics, survival status, clinical outcomes and the risk factors of patients diagnosed with COVID-19 who were admitted to the ICU of District Headquarter (DHQ) Hospital, Faisalabad (Pakistan) from 10 May to 10 July 2020.

METHODS

2.1 Inclusion criteria

According to the diagnostic and classification criteria of the National Institute of Health [NIH] Pakistan, the following criteria were used to enrol the patients admitted to the ICU of DHQ Hospital, Faisalabad, because of COVID-19-associated pneumonia:

1. Age ≥18 years.
2. Patients who met the diagnostic criteria of NIH Pakistan for COVID-19 infection, which are as follows:
   1. Clinical manifestations including fever and pulmonary symptoms (cough, shortness of breath, chest pain and tightness).
   2. Radiological findings of consolidation, ground-glass opacities (GGOs) either on chest X-ray or high-resolution computed tomography (HRCT).
   3. Real-time fluorescent reverse transcription-polymerase chain reaction (RT-PCR) of respiratory samples (nasal/oropharyngeal swab or tracheal secretions) positive for SARS-CoV-2. The laboratory confirmation of SARS-CoV-2 infection was carried out by the local health department.

2.2 Exclusion criteria

Following patients were excluded from the study:

1. Patients with negative detection for novel coronavirus nucleic acid.
2. Heart failure with pulmonary oedema (non-COVID heart disease).
3. Allergic pneumonia (acute or chronic eosinophilic pneumonia).
4. Patient refusal to be enrolled in the study.

2.3 Sample size

Twenty eligible confirmed cases of patients with COVID-19 were available to be enrolled in the study in the above time period.

2.4 Study design

This was a retrospective, cross-sectional, descriptive study conducted in the ICU of DHQ Hospital, Faisalabad (Pakistan), during the above time period.

The facility was designated as a referral centre by the provincial health department to cater to ~13 million population from the surrounding districts. The patients from these districts were referred to this facility for the management of patients with COVID-19.
2.5 | Data collection and procedure

A standardised data collection form was used to obtain patients' demographics, clinical manifestations and signs, laboratory indicators, treatment measures and clinical outcomes from their electronic medical records. This data form is a revision of the NIH Pakistan Severe Acute Respiratory and Emerging Infections Association Case Record Form Version. The recorded data included:

1. Demographics: Age, gender, body mass.
2. Underlying diseases: Chronic obstructive pulmonary disease, chronic kidney disease, cardiovascular disease, hypertension, diabetes, cerebrovascular disease, chronic liver disease, tumour.
3. Symptoms from onset to admission: Fever, cough, dyspnoea, fatigue or myalgia, diarrhoea.
4. Vital signs at admission to ICU: Heart rate, respiratory rate, oxygen saturation, Glasgow Coma Scale (GCS) score.
5. Laboratory tests at admission: Blood routine, coagulation profile, liver and kidney function tests, myocardial enzyme spectrum, atrial natriuretic peptide (BNP), infection indicators (C-reactive protein [CRP], procalcitonin [ProCT]).
6. Therapies: Continuous renal replacement therapy (CRRT), oxygen inhalation, non-invasive mechanical ventilation (NIV), invasive mechanical ventilation (IMV).
7. Complications: Acute respiratory distress syndrome (ARDS), acute heart injury, shock.
8. Hospital stay: Duration of stay in hospital prior to admission to ICU, duration of stay in ICU.

2.6 | Operational definitions

According to the provisional guidelines of the NIH Pakistan, the following definitions were employed in the study.

Moderate disease: Patients diagnosed with COVID-19 infection with any one of the following features:

1. Respiratory rate ≥30/min at rest.
2. Oxygen saturation (SpO₂) ≤93% on room air.
3. Arterial oxygen partial pressure (PaO₂)/oxygen uptake concentration (FiO₂) ≤300.

Severe disease: Patients with moderate disease criteria plus any one of the following:

1. Oxygen requirement of more than 10 litres for 90% saturation.
2. 50% of lung involvement on either chest X-ray or HRCT.
3. CRP >10 mg/L, D-dimer >1000 mg/mL, serum ferritin >1000 ng/mL.
4. Secondary infection (diagnosed by blood culture and sensitivity test or raised ProCT).
5. PaO₂/FiO₂ [PaO₂/FiO₂] (PF ratio) <118 mm Hg.

Critical disease: Patients with severe disease and any one of the following were labelled as having critical disease:

1. Shock
2. ARDS
3. Cardiac injury
4. Multi-organ dysfunction

Shock: Persistent hypotension despite volume resuscitation, requiring vasopressor to maintain mean arterial pressure (MAP) ± 65 mm Hg and serum lactate level ≥2 mmol/L. ARDS: As per the Berlin Definition of ARDS:

1. Onset: Within 1 week of a known clinical consultation.
2. Respiratory failure not fully explained by cardiac failure or fluid overload.
3. Bilateral opacities not fully explained by fluid overload, lobar or lung collapse or nodules.
4. Oxygen impairment with PF ratio <300 mm Hg.

Cardiac injury: Cardiac injury is diagnosed if the serum level of a cardiac marker (such as high-sensitivity troponin I) is higher than the 99th percentile upper reference limit, or the ECG and echocardiogram show new abnormalities. Multi-organ dysfunction: Acute life-threatening organ dysfunction with any of the following signs:

1. Altered mental status
2. Reduced urine output
3. Shortness of breath or increased respiratory failure
4. Signs of impending shock or circulatory failure
5. Decrease oxygen saturation
6. Laboratory evidence of coagulopathy
7. Thrombocytopenia
8. Acidosis
9. Raised lactate level
10. Deranged liver function and renal function

2.7 | Data analysis

Continuous variables were expressed as means with standard deviation and 95% confidence interval. Categorical variables were expressed as frequencies (percentages) with 95% confidence interval. Where appropriate, the t-test and chi-squared test (Fisher’s exact test where required) were used to compare the differences between the survival and death groups. Single-factor logistic analysis was used to explore the risk factors associated with hospital deaths. If the number of events was too small to calculate the odds ratio or there was collinearity between the variables, the variable was excluded from the univariate logistic analysis. A value of P < .05 was considered statistically significant unless otherwise stated.
3 | RESULTS

3.1 | Demographics

Twenty eligible patients diagnosed with severe COVID-19 pneumonia admitted to the ICU of DHQ Hospital, Faisalabad from 10 May to 10 July 2020 were included in the study. The mean age of the patients was 70 ± 12 years (35-85 years), 40% of them were male. The mean duration of symptoms before admission to the ICU of DHQ Hospital was 11 ± 9 days. The most common symptom on admission was cough. Other common symptoms include fatigue or myalgia (n = 18, 90%), fever (n = 17, 85%) and dyspnoea (n = 16, 80%). Six (30%) patients had more than one underlying disease. More than 50% (n = 11, 55%) of patients had underlying diseases, of which hypertension was the most common (n = 11, 55%), followed by cardiovascular diseases (n = 4, 20%) and diabetes (n = 3, 15%). Ten patients died during the ICU hospitalisation (hereinafter referred to as “death group”) and 10 patients recovered and were discharged (hereinafter referred to as “survival group”). Table 1 represents the demographics, clinical characteristics and laboratory indicators of the patients in each group.

3.2 | Laboratory parameters

Laboratory parameters showed that 11 patients (55%) developed lymphopenia (lymphocyte count < 0.8 x 10^9/L), of which 8 patients eventually died (P = .07). The baseline lymphocyte count of the survival group was significantly higher than that of the death group. Among the survivors, the lymphocyte count was the lowest on days 1-3 after hospitalisation; however, it improved during hospitalisation while persistent lymphopenia was observed in the death group. The white blood cell count in the death group showed a decreasing trend, and its mean value began to be higher than that in the survival group from 4 to 6 days after admission to the ICU of DHQ Hospital, Faisalabad.

The serum creatinine and blood urea nitrogen in the death group were significantly higher than those in the survival group, and the urine volume continued to decrease after 4-6 days of admission to the ICU. The D-dimer increased at admission to 6.91 ± 11.17 mg/mL in all patients and 15 (75%) patients had D-dimer > 1 mg/mL. Half of the patients had blood urea nitrogen > 7.1 μmol/L. The D-dimer of the survival group was significantly lower than that of the death group and began to show a downward trend from 9 to 11 days after admission to the ICU. Most patients had increased lactate dehydrogenase (LDH) (17 cases, 85%) and BNP (15 cases, 75%) at the time of admission, respectively 539.15 ± 455.85 U/L and 569.53 ± 8832.56 pg/mL.

In all patients, CRP was elevated to 101.46 ± 65.60 mg/L. The CRP in the survival group showed a significant downward trend after the admission to the ICU, while the CRP in the death group showed a significant upward trend as the disease worsened. The majority of the patients (17 cases, 85%) had high ProCT, 0.31 ± 0.42 ng/mL, of which 8 (40%) patients had 0.1 ≤ ProCT < 0.25 ng/mL and 7 (35%) patients had 0.25 ≤ ProCT < 0.5 ng/mL. Figure 1 shows the trends of laboratory indicators in the patients from the time of admission to the ICU.

3.3 | ICU treatment and clinical outcomes

The duration of stay in ICU was 15 ± 11 days. Most patients (n = 19, 95%) required oxygen inhalation in the ICU. Fourteen patients (70%) required NIV support. All 10 patients in the death group received NIV treatment, of which 6 (30%) received further IMV treatment. Six patients receiving IMV also received CRRT because of multi-organ dysfunction. Acute heart injury was the most common complication (n = 19, 95%), followed by shock (n = 12, 60%), ARDS (n = 12, 60%) and pneumothorax (n = 2, 10%). The death group patients were all considered complicated with shock and ARDS, and the probability of complicating shock and ARDS in the death group was significantly higher than that in the survival group (100% vs 20%, P = .001; 100% vs 20%, P = .001). Table 2 represents the treatment measures, complications and clinical outcomes of the patients.

3.4 | Risk factors for death

Half of the patients (10 patients) died between 2 and 19 days after admission to the ICU. Figure 2 shows the clinical course and outcome of each patient. Compared with dead patients, the average weight of the surviving patients was lower (61.70 ± 2.36 vs 68.60 ± 7.15 kg, P = .01) and the GCS score was higher (14.69 ± 0.70 vs 12.70 ± 2.45, P = .03). Univariate logistic analysis showed that increased body weight (OR = 1.39, 95% CI: 1.01-1.93) and decreased lymphocyte count (OR = 0.11, 95% CI: 0.01-0.84) were significantly associated with death among the patients. Table 3 represents the association of various factors with death in the regression model.

4 | DISCUSSION

Our study reports the analysis of clinical characteristics and outcomes of 20 confirmed patients with COVID-19 characterised by severe disease. Nine (45%) of these patients died within 35 days of admission to the hospital.

Our critically ill patients with COVID-19 were older which is in line with other studies.8,18 In previous studies involving patients with severe COVID-19, most common symptoms were fever, cough, fatigue and dyspnoea.6,9,11,18 Similarly, the incidence of cough, fatigue or myalgia, fever and dyspnoea on admission in our study were 95% (n = 19), 90% (n = 18), 85% (n = 17) and 80% (n = 16), respectively. In these patients, mean duration of symptoms was 11 ± 9 days from onset to ICU admission, and the previous studies reported similar (from 7 to 12 days) duration of symptoms prior to ICU admission.5,7,9,11
| Parameter                        | Total (n = 20) | Survival group (n = 10) | Death group (n = 10) | P value |

More than half of the patients (n = 11, 55%) in our centre had underlying diseases, similar to the data reported by the study from Wuhan (n = 64, 46%). However, a much higher percentage of patients has been reported in other studies. Similar to the previous studies, hypertension was the most common comorbidity, followed by cardiovascular disease and diabetes in our study. This requires more follow-up data for the observation of hypertension, the hypertension treatment received by the patient and the assessment of high-risk factors.

With regard to laboratory indicators, 11 (55%) patients in our centre developed lymphocytopenia on admission and it mainly occurred in the death group (n = 8). Decreased lymphocyte count was significantly associated with the death of patients with COVID-19 in ICU. This is consistent with the results of a single-factor analysis of the retrospective study from Wuhan. Previous studies of SARS and Middle East respiratory syndrome (MERS) have also found lymphopenia in their studies. Studies have confirmed that lymphopenia is one of the earliest changes in SARS and a reliable prognostic indicator of SARS. In addition, studies have also shown that MERS coronavirus can induce T-cell apoptosis through the activation of apoptotic pathways. In several previous studies on moderate disease patients infected with SARS-CoV-2, only 35% and 40% of patients had mild lymphopenia, whereas in other studies severe SARS-CoV-2-associated lymphopenia occurred in more than 70% and 80% of the infected patients, suggesting that lymphopenia may reflect the severity of SARS-CoV-2 infection.

Most critically ill patients in our centre had an increased LDH (n = 17, 85%) when they were admitted, slightly higher than the 76% and 67% observed in patients from the other studies. All patients in our study had elevated D-dimers on admission and 15 (75%) patients had D-dimers > 1 mg/L. However, in the study of patients with moderate COVID-19, only 36% had an increase in D-dimer. Another early study from Wuhan also showed that ICU patients had a higher level of D-dimer (median D-dimer level of 2.4 mg/L) than non-ICU patients (median D-dimer level of 0.5 mg/L). Studies have also found that D-dimer >1 mg/L has been associated with increased mortality of patients. Our study did not observe differences between the survival and death groups in terms of D-dimer, which may be related to small sample size. The CRP of all patients in our study was increased to 101.46 ± 65.60 mg/L, which was much higher than the average CRP in patients with moderate COVID-19, 51.4 ± 41.8 mg/L. The probability of CRP increase (100%) was also higher in our study than that of patients with moderate COVID-19, 60.7% and 86%. Similarly, the probability of elevated ProCT (85%, n = 17) was much higher in our study than the 6% to 30% probability found in patient with moderate COVID-19 studies. It is, therefore, suggested that secondary bacterial infection may be a complication in severe patients and cannot be disregarded.

Mechanical ventilation is the main supportive treatment for critically ill patients with COVID-19. In our study, only six patients (30%) received further IMV treatment, which is much lower than reported in other ICU patients: 88% (Lombardy, Italy), 47% (Wuhan), 42% (Wuhan) and 30% (Wuhan). Non-invasive ventilation was used...
more frequently, with 70% of patients receiving NIV in our study, as compared with the rate of NIV use in other ICU studies: 42% (Wuhan), 56% (Wuhan) and 62% (Wuhan).

Acute hypoxemic respiratory failure caused by ARDS has been found to be the most common complication (60%-70% of patients admitted to the ICU), followed by shock (30%), myocardial
dysfunction (20%-30%) and acute kidney disease injury (10%-30%) [5,6 9-11]. In our study, acute heart injury was the most common (19 cases, 95%), followed by ARDS (12 cases, 60%), shock (12 cases, 60%) and pneumothorax (2 cases, 10%). A study of patients with mild COVID-19 in Wuhan reported that 53% of patients in their cohort died of respiratory failure, 7% died of shock (probably caused by fulminant myocarditis) and 33% of patients died of both conditions.21 In our study, the 10 patients in the death group were all complicated with shock and ARDS. The probability of death and ARDS in the death group was much higher than that in the survival group. Because of the limited sample size, this study failed to show the association of concurrent ARDS or shock with the death of patients. We speculate that concurrent ARDS and shock may be related to the death of patients with severe COVID-19. Because of the limitation of sample size and lack of laboratory data, our study found that only increased BMI and decreased lymphocyte count were significantly associated with an increased chance of death in patients with COVID-19 in the ICU.

This study had several limitations. First, the study was conducted in a single centre and was limited by the time of follow-up. Only 20 patients with serious and critical COVID-19 were included. Smaller sample size may reduce the reliability of the statistical analysis. Second, there was a lack of detailed medical and treatment information during the hospitalisation of patients, such as mechanical ventilation parameters, blood gases, patient medication, imaging examinations and other supportive treatments. Finally, this is a retrospective study that failed

Abbreviations: ARDS, acute respiratory distress syndrome; CRRT, continuous renal replacement therapy; IMV, invasive mechanical ventilation; NIV, non-invasive mechanical ventilation.

**FIGURE 2** Clinical course and outcome of 20 patients with COVID-19 admitted to the ICU.
to include adequate laboratory tests on all patients, including interleukin 6, serum ferritin, etc., resulting in an inability to assess their role in predicting hospital deaths. The findings of our study can be utilised by future studies to further investigate the clinical course and outcome of hospitalised patients with COVID-19 in ICU. However, a prospective multicentre study with a larger sample size is necessitated to further explore the factors associated with nosocomial death in patients with severe COVID-19.

5 | CONCLUSION

In summary, critically ill patients with COVID-19 tend to be relatively older. Hypertension is the most common underlying condition in critically ill patients with COVID-19. The mortality rate is high in critically ill patients with COVID-19. Lower GCS score, higher body weight and decreased lymphocyte count appear to be potential risk factors for the death of patients with COVID-19 in the ICU.
