Conformally invariant boundary conditions for minimal models on a cylinder are classified by pairs of Lie algebras \((A,G)\) of ADE type. For each model, we consider the action of its (discrete) symmetry group on the boundary conditions. We find that the invariant ones correspond to the nodes in the product graph \(A \times G\) that are fixed by some automorphism. We proceed to determine the charges of the fields in the various Hilbert spaces, but, in a general minimal model, many consistent solutions occur. In the unitary models \((A,A)\), we show that there is a unique solution with the property that the ground state in each sector of boundary conditions is invariant under the symmetry group. In contrast, a solution with this property does not exist in the unitary models of the series \((A,D)\) and \((A,E_6)\). A possible interpretation of this fact is that a certain (large) number of invariant boundary conditions have unphysical (negative) classical boundary Boltzmann weights. We give a tentative characterization of the problematic boundary conditions.

I. INTRODUCTION

It has been an extremely fruitful idea to study a conformal field theory by putting it on various surfaces, with or without boundaries. Apart from the sphere, that has been considered first, prime examples of non–trivial geometries include the torus \(\mathbb{T}\) and the cylinder \(\mathbb{C}\). They serve to probe different facets of a given conformal theory. However the data specific of these surfaces are inextricably related to each other, and this fact provides very stringent constraints on the theory itself, allowing for example to determine its field content.

For minimal conformal theories, the problem on the torus for single–valued fields has been resolved in \(\mathbb{T}\): consistent models have a periodic partition function that can be associated in a unique way with a pair \((A,G)\) of simple Lie algebras of ADE type.

The solution of the analogous problem for the cylinder is much more recent, even if early calculations in either specific models or with specific boundary conditions have been carried out in \(\mathbb{C}\). The recent discovery in \(\mathbb{C}\) of a new conformally invariant boundary condition in the 3–state Potts model triggered a renewal of interest in the problem. For minimal models, its solution was given in \(\mathbb{C}\), and shown to be encoded in the same Dynkin graphs that specify the torus partition function.

When a model has a symmetry, necessarily discrete in this context, fields can be multiple–valued on the torus, so that non–periodic sectors exist. Furthermore, the fields transform under the symmetry group, and, upon diagonalization, can be assigned charges. All this information is encoded in frustrated partition functions, covariant under the modular group of the torus, a fact that can be used to, first, detect the presence of a symmetry, and then to compute the various partition functions.

In this article, we address the question of the action of the symmetry group on the cylinder partition functions for the minimal models. We show how the symmetry group acts on the boundary conditions, and identify the invariant (or symmetric) ones. We then study the charge assignments of the fields that occur in the presence of those boundary conditions.

Section II is a reminder about the minimal conformal models on a torus and on a cylinder. In Section III, we discuss the action of the symmetry group on the conformally invariant boundary conditions, which is then used in Section IV to compute frustrated partition functions on a cylinder, or equivalently the charge assignment of the boundary fields. Section V contains explicit formulae and computational details of a particular assignment. Its unicity (in fact non–unicity) is examined in Section VI, from which we conclude that, in general, a large number of distinct charge assignments are consistent. We also derive selection rules for the boundary fusion coefficients. We finish, in Section VII, with an analysis of the unitary models for which we propose an unambiguous charge assignment.

Section VII contains the most interesting corollary of the previous sections. An analysis based on the expected consequences of the Perron–Frobenius theorem fixes a unique charge assignment in the unitary \((A,A)\) models, which we conjecture to be the correct one. This is in sharp contrast with the models of the \((A,D)\) and \((A,E_6)\) series. For those, there is no consistent charge assignment that is compatible with the Perron–Frobenius theorem, the reason being that there is no way to ensure an invariant ground state in all sectors. Motivated by the results obtained for the Potts model \(\mathbb{C}\), we will interpret this phenomenon as the non–existence of positive classical Boltzmann weights for some invariant boundary conditions.

II. MINIMAL MODELS

Minimal models are classified by a pair \((A, G)\) of simply–laced simple Lie algebras with coprime Coxeter numbers, \(p\) and \(q\). One may assume that \(p\) is odd. Their periodic partition function on a torus of modulus \(\tau\) is a sesquilinear form in the Virasoro characters

\[
Z(A, G) = \sum_{i,j} M_{ij} \chi_i^*(\tau) \chi_j(\tau), \quad M_{ij} \in \mathbb{N},
\]

where \(i, j\) are labels for Virasoro highest weight representations. They lie in the Kac table \({(r, s) : 1 \leq r \leq p - 1, 1 \leq s \leq q - 1}\), in which \((r, s)\) and \((p - r, q - s)\) must be identified. The connection with the Lie algebras is best brought out by writing the diagonal elements \(M_{ii}\) as

\[
Z(A, G) = \frac{1}{2} \sum_{r \in \text{Exp } A, s \in \text{Exp } G} |\chi_{r,s}|^2 + \text{off–diagonal},
\]

where \(r\) and \(s\) run over the exponents of \(A\) and \(G\). The full expressions of the partition functions are given in \[2\].

The question of the symmetry group has been first addressed in \[2\], and solved in \(v\) for the unitary models with \(|p - q| = 1\). The analysis can however be easily extended to the non–unitary minimal models, with the following result. With the exception of the models \(A_{p-1}, A_{q-1}\) with \(p\) and \(q\) odd, which have no symmetry at all, the other models \(A, G\) have a finite symmetry group \(\Gamma\), which is the group of automorphisms of the Dynkin graph of \(G\), that is, \(\Gamma(G) = Z_2\) except \(\Gamma(D_4) = S_3\) and \(\Gamma(E_7, E_8) = \{e\}\).

When a model has a symmetry group, the fields may have a non–trivial monodromy along the two periods of the torus, transforming as \(\phi(z + 1) = g \phi(z)\) and \(\phi(z + \tau) = g' \phi(z)\) for two commuting elements \(g, g'\). In the Hamiltonian formalism, this amounts to give a Hilbert space \(\mathcal{H}_g\) of states with a \(g\)–monodromy along the first period, which are then acted on by \(g'\) when transported along the second period. The latter action can be diagonalized, \(g' |\phi\rangle = e^{z_{2\pi}/N} |\phi\rangle\), defining the charge \(Q\) of the field \(\phi\) under the action of \(g'\), an element of order \(N\).

The field content of \(\mathcal{H}_g\) as well as their charges can be read off from the frustrated partition functions \(Z_{g,g'}(A, G)\). These are still sesquilinear forms but with coefficients in \(\mathbb{Z}(e^{2\pi i/|\Gamma|})\):

\[
Z_{g,g'} = \text{Tr}_{\mathcal{H}_g} \left[ q^{L_0-c/24} q^{L_{-c/24}} g' \right].
\]

Because a modular transformation mixes the two periods, it must be accompanied by a corresponding change of monodromies so that the net effect vanish (for a fixed pair \((A, G)\)):

\[
Z_{g,g'}(\tau) = Z_{g^a g'^c, g^b g'^d} (\frac{a \tau + b}{c \tau + d}).
\]

All such functions are given explicitly in \[10\] (with a straightforward extension to the non–unitary case). The function \((2.3)\) corresponds to \(g = g' = e\).

On a cylinder, say of length \(L\) and perimeter \(T\), only one Virasoro algebra remains, so that the partition function is linear rather than sesquilinear in the characters \[2\]. Conformally invariant boundary conditions \(\alpha, \beta\) must be prescribed on the two boundaries, and a monodromy condition \(g\) must be imposed along the periodic coordinate, \(\phi(z + T) = g \phi(z)\). We first consider a trivial monodromy, \(g = e\).

If the time variable is defined to run along the periodic direction, the partition function is the trace of the transfer matrix \(e^{-TH_{\alpha, \beta}}\):

\[
Z^c_{\alpha, \beta}(\tau) = \sum_i n^i_{\alpha, \beta} \chi_i(\tau), \quad \tau = iT/2L.
\]

The integer \(n^i_{\alpha, \beta}\) gives the multiplicity of the primary field with Kac label \(i\) in the Hilbert space \(\mathcal{H}_{\alpha, \beta}\).

Alternatively, one may view the time evolution as going from one boundary to the other. In this case, the states on constant time surfaces belong to the bulk periodic Hilbert space \(\mathcal{H}_c\), and are propagated in time from one boundary state \(|\alpha\rangle\) to the other \(|\beta\rangle\) (formally also in \(\mathcal{H}_c\)). The partition function is then

\[
Z^c_{\alpha, \beta}(\tau) = \langle \beta | e^{-cH} | \alpha \rangle,
\]

with \(H_c\) the Hamiltonian corresponding to periodic bulk sector.

The boundary states are conformally invariant, satisfying \((L_n - \vec{L}_{-n})|\alpha\rangle\) for all \(n \in \mathbb{Z}\) \[11\]. The solutions to this equation are the Ishibashi states \[11\]: every highest weight representation \(|i \otimes \bar{i}\rangle\) contains exactly one such state, which we denote by \(|i\rangle\), while the other representations \(|i \otimes j\rangle\), for \(i \neq j\), do not contain any. In the present situation, the Ishibashi states must be taken from the space \(\mathcal{H}_c\), and hence are labelled by \(\mathcal{E}_c = \{i : i \otimes \bar{i} \in \mathcal{H}_c\}\).

Expanding the boundary states in the basis of Ishibashi states, \(|\alpha\rangle = \sum_i c^i_\alpha |i\rangle\), makes the partition function \((2.6)\) take the form

\[
Z_{\alpha, \beta}(\tau) = \sum_{i \in \mathcal{E}_c} c^i_\alpha c^\dag_i \chi_i(\frac{1}{T}).
\]

The arguments of the characters in \((2.5)\) and \((2.7)\) are related by the modular transformation \(\tau \mapsto \frac{-1}{\tau}\), under

\[1\] That forces us to focus on Abelian subgroups of \(\Gamma\). Thus in this paper we consider \(Z_2\) and \(Z_3\) (sub)groups only.
which the characters transform linearly through a unitary matrix \( S \). Comparing the two formulae then yields Cardy’s equation

\[
n^i_{\alpha,\beta} = \sum_{j \in \mathcal{E}_r} S_{i,j} c^i_{\alpha} c^j_{\beta}. \tag{2.8}
\]

The relations (2.8) are overdetermined for the vectors \( c^j \), and provide a means to classify the boundary conditions \(|\alpha\rangle\), to compute the spectra of \( \mathcal{H}_{\alpha,\beta} \), and in turn the surface scaling dimensions. Such calculations have been carried out in [2,4], but the general answer appeared only very recently in [7,8]. Let \( 1 \) be the label corresponding to the vacuum state, namely to \((r,s) = (1,1) = (p-1,q-1)\).

In [8] it was observed that, upon setting \( c^i_{\alpha} = \psi^i_{\alpha}/\sqrt{S_{1,i}} \) for a set of complete and orthonormal vectors \( \psi^i \), Cardy’s equation appears as an explicit diagonalization

\[
n^i_{\alpha,\beta} = \sum_{j \in \mathcal{E}_r} \psi^j_{\beta} S_{i,j}/\sqrt{S_{1,j}}. \tag{2.9}
\]

The matrices \( n^i \) have eigenvalues \( S_{i,j}/S_{1,j} \), and a common eigenbasis is given by the vectors \( \psi^i \). As a result, they satisfy the fusion rules

\[
n^i n^j = \sum_k N^k_{ij} n^k. \tag{2.10}
\]

Reversing the argument, the authors of [8] conclude that an \( \mathbb{N} \)-valued representation of the fusion algebra of dimension \(|\mathcal{E}_r|\) provides a solution to Cardy’s equation with \(|\mathcal{E}_r|\) different boundary conditions. When \( c^i_{\alpha} = \psi^i_{\alpha}/\sqrt{S_{1,i}} \) is an invertible matrix, this solution yields the maximal set of conformally invariant boundary conditions. Note that the boundary states \(|\alpha\rangle\) are determined up to a phase, but the fact that the entries of \( n^i \) are to be positive integers leaves only a global, unobservable, phase.

For minimal models, this was all made explicit in [3]. For the model \((A,G)\), it was shown that each node in the product Dynkin diagram \( A \times G \), quotiented by an appropriate \( Z_2 \) automorphism, defines a boundary condition and vice-versa. Indeed, from [22], the number of Ishibashi states in the periodic sector is \(|\mathcal{E}_r| = 2^{|\mathbb{E}|} \exp(A \times \exp(G)) \), so that only half the nodes can define distinct boundary conditions. We will use the variables \( \alpha, \beta \) and \((a_i,b_j)\) as labels for the nodes of \( A \times G \). The letters \( A \) and \( G \) will denote at the same time the Lie algebras, the Dynkin diagrams or the corresponding adjacency matrices.

As a result of the quotient of the product graph, the matrices \( n^i \), for \( i = (r,s) \), are given by [3]

\[
n^i_{(a_1,b_1),(a_2,b_2)} = (\hat{N}_r)_{a_1,a_2} (V_s)_{b_1,b_2} + (N_r)_{a_1,a_2} (V_s)_{b_1,b_2} = n^i_{(a_1,b_1),(a_2,b_2)} = n^i_{(a_1,b_1),(a_2,b_2)}. \tag{2.11}
\]

In this formula, the \( \hat{N}_r \)'s and the \( V_s \)'s are the fused adjacency matrices of \( A \) and \( G \) respectively. They are defined recursively by \( X_m = X_2 X_{m-1} - X_{m-2} \), with \( X_1 = 1 \) and \( X_2 = A \) if \( X = \hat{N} \), and \( X_2 = G \) if \( X = V \). Equivalently,

\[
\hat{N}_r = U_{r-1}(A), \quad V_s = U_{s-1}(G), \tag{2.12}
\]

where \( U_m(2 \cos x) = \sin ((m+1)\pi/x) \) is the \( m \)-th Tchebychev polynomial of the second kind. The automorphism \((a,b) \mapsto (a^*,b^*) \) can be determined from the condition \( n^{(r,s)} = n^{(p-r,q-s)} \) (necessary if the \( n^i \) are to satisfy the fusion algebra). It yields \( a^* \) and \( b^* \) to be given by the non-trivial automorphism of \( A \) and \( G \), for \( G \neq D_{\text{even}}, E_7, E_8 \), and \( b^* = b \) for \( G = D_{\text{even}}, E_7, E_8 \).

Viewing the tensor products \( F^i(A,G) = \hat{N}_r \otimes V_s \) as the fused adjacency matrices of \( A \times G \), the above result may be summarized by saying that \( n^i \) is a folded fused adjacency matrix of \( A \times G \)

\[
n^i_{\alpha,\beta} = F^i_{\alpha,\beta} (A,G) + F^i_{\alpha,\beta^*} (A,G). \tag{2.13}
\]

The eigendata for the matrices \( A \) and \( G \) make sure that the matrices in (2.11) satisfy the minimal model fusion relations. For the \((A,G)\) models, the \( a_i \) (resp. \( b_i \)) labels run over the same set as \( r \) (resp. \( s \)), and the matrices \( n^i \) are the fusion matrices \( N^i \) themselves.

### III. SYMMETRIC BOUNDARY CONDITIONS

We now proceed to the analysis of the cylinder partition functions when there is a group of symmetry \( \Gamma \). From now on, we thus take \( q \) even, and \( G \neq E_7, E_8 \).

The boundary states are combinations of periodic Ishibashi states, on which the action of \( \Gamma \) is known from the torus partition functions \( Z_{e,g} \). This induces an action on the boundary states which one can determine. That action must be by permutations.

For the minimal models, a boundary state corresponds to a pair of nodes of \( A \) and \( G \),

\[
\langle (a,b) \rangle = \sum_{i \in \mathcal{E}_r} \frac{1}{\sqrt{S_{1,i}}} \psi^i(a,b | i)). \tag{3.1}
\]

where the \( \psi^i \) form an eigenbasis for the concrete matrices in (2.11).

Let us denote by \( \sigma \) the automorphisms of the Dynkin graph of \( G \), so that every \( \sigma \) has fixed points. (The automorphism of the \( A \) factor has a free action, and is used to obtain a set of representatives under the \( * \) involution, see (2.11)). Each \( \sigma \) has a diagonalizable action on the eigenvectors \( \psi^i \).

The action of \( g \in \Gamma \) on a periodic Ishibashi state can be read off from the diagonal terms in the frustrated partition function \( Z_{e,g}(A,G) \) [11]. These can be compactly

\[2\text{The automorphism } * \text{ in } G \text{ thus coincides with the charge conjugation in the corresponding affine algebra } G.\]
presented as follows. If \( g \) has order \( N \), and if one writes the diagonal terms in \( Z_{g,e} \) as
\[
Z_{g,e} = \sum_{i \in \mathcal{E}_e} c_{N}^{g,(i)} |\chi_i|^2 + \ldots, \tag{3.2}
\]
then, for a proper choice of the \( \psi^i \), the phase is seen to be exactly equal to the eigenvalue of \( \psi^i \) under an order \( N \) automorphism \( \sigma \):
\[
\psi^i(a, \sigma(b)) = c_{N}^{g,(i)} \psi^i(a, b). \tag{3.3}
\]
The \( \sigma \) that is induced by \( g \) through the previous formula is unambiguous in the models \((A, G)\) if \( G \) is not \( D_4 \): the only non–trivial \( g \) induces the only non–trivial \( \sigma \). When the \( D_4 \) algebra is involved, exactly which \( \sigma \) in \( S_3 \) arises from a set of charges \( Q_g \) (uniquely given by \( Z_{g,e} \)) depends on the eigenbasis we choose. In particular, a same set of \( Z_2 \) charges can lead to the three different (but conjugate) order two \( \sigma \)'s.

It quickly follows from (3.1) and (3.3) that an order \( N \) group element \( g \) acts on the boundary states as an order \( N \) automorphism \( \sigma \):
\[
|\chi(a, b)\rangle \rightarrow \left|\varphi(a, b)\right\rangle = |(a, \sigma(b))\rangle. \tag{3.4}
\]
Therefore, for any subgroup \( \gamma \) of \( \Gamma \), the \( \gamma \)-symmetric boundary conditions correspond to the nodes of \( A \times G \) that are fixed by a group \( \gamma \) of automorphisms of \( G \). This set of nodes form a graph which we call the fixed point graph and denote by \( A \times G^\gamma \).

In particular, the boundary conditions that are invariant under a group element \( g \) correspond to the nodes in \( A \times G^g \), with \( G^g \) the part of \( G \) that is fixed by the automorphism \( \sigma \) induced by \( g \). As before the pairs of nodes which are related by the \( ^* \) automorphism define the same invariant boundary conditions. In the minimal models, the fixed point diagrams that arise for the various choices of \( g \) are
\begin{align*}
(A_{p-1}, A_{q-1}) & : T_{(p-1)/2} \times A_1, \\
(A_{p-1}, D_{q/2} + 1) & : T_{(p-1)/2} \times A_{q/2} - 1, \quad (g^2 = e), \\
(A_{p-1}, D_4) & : T_{(p-1)/2} \times A_1, \quad (g^3 = e), \\
(A_{p-1}, E_6) & : T_{(p-1)/2} \times A_2, 
\end{align*}
where \( T_{(p-1)/2} \) denotes the tadpole diagram obtained by quotienting \( A_{p-1} \) by its automorphism \( ^* \).

For instance, the fixed point graph of an element \( g \) of order two in the \((A_{p-1}, D_{q/2} + 1)\) model is graphically given by
\[
\begin{array}{c}
\bullet \quad \bullet \\
\bullet \quad \bullet \\
\bullet \quad \bullet
\end{array}
\quad \times 
\begin{array}{c}
\bullet \quad \bullet \\
\bullet \quad \bullet \\
\bullet \quad \bullet
\end{array}
\]

IV. CYLINDER PARTITION FUNCTIONS

The consequences of a symmetry can now be pursued at the level of the partition functions. Let us suppose that \( \alpha \) and \( \beta \) are two boundary conditions that are invariant under a group element \( g \), of order \( N \).

It implies that the transfer matrix \( e^{-H_{\alpha,\beta}} \) and \( g \) commute, and can be diagonalized in the same basis. The effect, on the cylinder partition function, of the insertion of \( g \) on a line connecting the two boundaries is to affect each Virasoro tower with a \( N \)-th root of unity, so that the first form (2.3) becomes
\[
Z^g_{\alpha,\beta}(\tau) = \sum_i n^{(g) i}_{\alpha,\beta} \chi_i(\tau). \tag{4.1}
\]
This shows that \( n^{(g) i} \) must be related in the following way to the restriction of \( n^i \) to the \( g \)-symmetric boundary conditions: an entry of \( n^i \) equal to \( n \) becomes in \( n^{(g) i} \) a sum of \( n \) \( N \)-th roots of unity.

In the second form, the boundary state \( |\alpha\rangle \) is propagated to \(|\beta\rangle\) by the Hamiltonian that acts on the bulk sector twisted by \( g \), so that
\[
Z^g_{\alpha,\beta}(\tau) = \langle \beta | e^{-LH^*} |\alpha\rangle. \tag{4.2}
\]
This formula makes it clear that the states \( |\alpha\rangle \) and \(|\beta\rangle\) should have a projection in the twisted Hilbert space \( H_g \), and being conformally invariant, must have expansions in Ishibashi states of the bulk \( g \)-sector, themselves labelled by \( \mathcal{E}_g = \{ i : [i \otimes \bar{g}] \in H_g \} \). Setting \( |\alpha\rangle = \sum_i \psi_{\alpha i}^g |i\rangle_g \), one obtains a Cardy equation
\[
n^{(g) i}_{\alpha,\beta} = \sum_{j \in \mathcal{E}_g} S_{i,\bar{j}} \psi_{\alpha}^g j \psi_{\beta}^g j, \tag{4.3}
\]
for all boundary conditions which are \( g \)-symmetric.

By inspecting the torus partition functions \( Z_{g,e}(A, G) \) \footnote{See also the next section}, one readily sees that the matrices \( c_{(g) i}^\alpha \) are square, namely
\[
|\mathcal{E}_g| = \frac{1}{2} |A \times G^g| = |T \times G^g|, \tag{4.4}
\]
where the factor \( \frac{1}{2} \) accounts for the identification under \( ^* \). Let us also note that, since the \( g \)-Ishibashi states form a basis for boundary states that are invariant under \( g \), they should themselves be all neutral for consistency. This is again easily checked from \( Z_{g,g} \).

The rest of this article is devoted to a discussion of the solutions to the Cardy equation (4.3). We will suggest that the proper physical solution is a natural generalization to \( g \neq e \) of the two formulae (2.9) and (2.13) for \( n^i \).

Our first statement is that a particular solution, compatible with \( n^i \equiv n^{(g) i} \), is provided, modulo a sign \( \delta_i \), by the folded fused adjacency matrices of the graph \( A \times G^g \):
\[
s^{(g) i}_{\alpha,\beta} = \delta_i \left[ F^i_{\alpha,\beta}(A, G^g) + F^i_{\alpha,\beta} (A, G^g) \right], \quad \delta_i = \pm 1. \tag{4.5}
\]
Here \( \alpha = (a_1, b_1) \) and \( \beta = (a_2, b_2) \) are pairs of nodes in \( A \times G^g \) (with the usual identification under \( ^* \)), and the automorphism \( ^* \) is the same as before.
When \( g, \sigma \neq e \), this formula can be simplified because every \( b_2 \) in \( G^\sigma \) is a fixed point of \(*\). Indeed since \( \beta \) is a node of \( A \times G^\sigma \), \( b_2 \) is a fixed point of \( \sigma \). But \( \sigma \) and \(*\) coincide, except for \( G = D_{\text{even}} \) for which \(*\) is trivial. Thus the folding by \(*\) acts on \( a_2 \) only, resulting in an effective folding of the \( A \) factor onto a \( T \) graph (hence the graphs \((3.3)\)). One also checks that the folded fused adjacency matrices of \( A_{p-1} \) are the fused adjacency matrices of \( T_{(p-1)/2} \). Thus the matrices in \((4.3)\) are simply proportional to the fused adjacency matrices of the fixed point diagram

\[
\bar{n}_{\alpha,\beta}^{(g)i} = \delta_i \hat{F}_{\alpha,\beta}(T,G^\sigma) = \delta_i U_{r-1}(T)_{a_1,a_2} U_{s-1}(G^\sigma)_{b_1,b_2}.
\]

(4.6)

The matrices \( F^i(T,G^\sigma) \) fall short of satisfying the minimal fusion algebra, but the factors \( \delta_i \) can be adjusted so that the \( \hat{n}_{\alpha,\beta}^{(g)i} \) do satisfy it.

The fusion algebra of the minimal model \( \mathcal{M}(p,q) \) is polynomially generated by two generators \( X \) and \( Y \), which one can associate with the representatives of \( N^{(2,1)} \) and \( N^{(1,2)} \). The other elements of the algebra are explicitly given by Tchebychev polynomials

\[
N^i = U_{r-1}(X) U_{s-1}(Y),
\]

and the generators must satisfy three relations:

\[
U_{p-1}(X) = U_{q-1}(Y) = U_{p-2}(X) - U_{q-2}(Y) = 0.
\]

(4.8)

The matrices \( F^i(T,G^\sigma) \) have the proper form \((4.7)\), and \( T_{(p-1)/2} \) and \( G^\sigma \) do indeed satisfy the first two relations in \((4.8)\). This is most easily seen by verifying that all eigenvalues satisfy the relevant equation. For instance, the eigenvalues \( \lambda_m \) of \( T_{(p-1)/2} \) are in

\[
\text{spec}(T^{(p-1)/2}) = \{ 2 \cos \frac{\pi m}{p} : 1 \leq m \text{ odd} \leq p-1 \},
\]

(4.9)

and clearly satisfy \( U_{p-1}(\lambda_m) = 0 \).

In the same way, one computes that

\[
U_{p-2}(T^{(p-1)/2}) = 1.
\]

(4.10)

The corresponding calculation for \( G^\sigma \) yields\(^3\) in the same four cases as in \((4.3)\),

\[
\begin{align*}
G^\sigma = A_1 : & \quad U_{p-2}(G^\sigma) = (-1)^{\frac{p+1}{2}} 1, \\
G^\sigma = A_{\frac{p}{2} - 1} : & \quad U_{q-2}(G^\sigma) = -1, \\
G^\sigma = A_1 : & \quad U_{q-2}(G^\sigma) = 1, \\
G^\sigma = A_2 : & \quad U_{10}(G^\sigma) = -1,
\end{align*}
\]

(4.11)

where the last line refers to the models \((A_{p-1}, E_6)\) for which \( q = 12 \). Thus, except when \( G^\sigma = A_1 \) and when \( q = 2 \mod 4 \), the last condition in \((4.8)\) is not fulfilled.

Owing to the parity properties of the Tchebychev polynomials, \( U_m(-x) = (-1)^m U_m(x) \), one easily sees that \( X = (-1)^{\frac{p+1}{2}} T_{(p-1)/2} \) in the first and third cases of \((4.11)\), and \( X = -T_{(p-1)/2} \) in the second and fourth ones, together with \( Y = G^\sigma \), do satisfy all three conditions and therefore generate the correct algebra.

Correspondingly, one finds that the matrices \( \hat{n}_{\alpha,\beta}^{(g)i} = F^i(X,Y) = \delta_i F^i(T,G^\sigma) \) with the following signs,

\[
\begin{align*}
(A_{p-1}, A_{q-1}) : & \quad \delta_i = (-1)^{(r+1)(\frac{p-1}{2} + 1)}, \\
(A_{p-1}, D_{\frac{p}{2} + 1}) : & \quad \delta_i = (-1)^{r+1}, \\
(A_{p-1}, D_4) : & \quad \delta_i = 1, \\
(A_{p-1}, E_6) : & \quad \delta_i = (-1)^{r+1}.
\end{align*}
\]

(4.12)

obey the minimal fusion algebra. Because of the signs \( \delta_i \) but also because the matrices \( F^i(T,G^\sigma) \) are not positive for \( \sigma \neq e \) (they are however of constant sign), the \( \hat{n}_{\alpha,\beta}^{(g)i} \) provide \( \mathbb{Z} \)-representations\(^4\) of the minimal fusion algebra.

It remains to prove our earlier assertion that the so–defined \( \hat{n}_{\alpha,\beta}^{(g)i} \) are solutions to Cardy’s equation \((4.3)\).

Since they satisfy the fusion algebra, the \( \hat{n}_{\alpha,\beta}^{(g)i} \) must have eigenvalues given by ratios \( \frac{\psi_{\alpha,\beta}^{(g)i}}{S_{\alpha,\beta}} \) of \( S \) matrix elements. It is not difficult to see, by looking first at the partition functions \( Z_{g,e} \) to get \( \hat{E}_g \) and then by computing the ratios explicitly, that the eigenvalues of \( \hat{n}_{\alpha,\beta}^{(g)i} \) are precisely the above ratios for \( j \in \hat{E}_g \) (see next section). Thus the following diagonalization formulae hold

\[
\hat{n}_{\alpha,\beta}^{(g)i} = \sum_{j \in \hat{E}_g} \psi_{\alpha,\beta}^{(g)i} S_{\alpha,\beta,j} \frac{S_{\alpha,j}}{S_{\alpha,\beta}} \psi_{\alpha,\beta}^{(g)i},
\]

(4.13)

where the vectors \( \psi_{\alpha,\beta}^{(g)i} \) form a common orthonormal eigenbasis (also common to all fused adjacency matrices \( F^i(T,G^\sigma) \) of the fixed point diagram). This yields the value of the coefficients in \((4.3)\)

\[
\psi_{\alpha,\beta}^{(g)i} = \frac{1}{\sqrt{S_{\alpha,\beta,j}}} \psi_{\alpha,\beta}^{(g)i}.
\]

(4.14)

To complete the proof, it is enough to show that they are compatible with the \( n^i \), in the sense that has been explained in Section \( III \): an entry in \( n^i \) equal to \( n \) goes over, in \( \hat{n}_{\alpha,\beta}^{(g)i} \), to a sum of \( n \) roots of unity, and moreover \( \hat{n}_{\alpha,\beta}^{(g)i} = 1 \). One may verify that this is indeed the case. We omit the proof here since, to a large extent, it is given in the next section.

\(^3\)The adjacency matrix of \( A_1 \) is the number zero, so that its fused adjacency matrices are \( U_{s-1}(0) = (-1)^{(s-1)/2} \) for \( s \) odd, and 0 for \( s \) even.

\(^4\)In case of a \( Z_3 \) symmetry group, one might expect \( \mathbb{Z}(e^{2\pi i/3}) \)–valued representations. This is however excluded by the symmetry \( Z_{\alpha,\beta}^g = Z_{\beta,\alpha}^g \) (time reversal invariance), which implies the reality of \( n_{\alpha,\beta}^{(g)i} \).
We examine in turn each of the three infinite series.

The frustrated partition functions are \[ n^i(\pm 1), n^i(2), n^i(\mp 1) = N^i(\pm 1)/(a_1, a_2), \]
for all odd \( s \), and identically equal to zero for \( s \) even. This then leads to

\[
\tilde{n}^i(\pm 1) = (-1)^{(r+s+1)q} N^i(\pm 1), \quad \text{for odd } n \text{ and identical to zero for } n \text{ even.}
\]

This equation shows clearly that \( \tilde{n}^i(\pm 1) \) is compatible with \( n^i \) in the sense explained before.

V. MORE EXPLICIT FORMULAE

We give here the computational details and the proofs that were missing in the previous section.

We begin by recalling the formula giving the \( S \) matrix elements in the minimal model \( \mathcal{M}(p, q) \), for \( i = (r, s) \) and \( j = (r', s') \),

\[
S_{i,j} = \sqrt{\frac{\pi p q}{r}} (-1)^{r s' + r' s + 1} \sin \frac{\pi q r'}{p} \sin \frac{\pi p s r'}{q}. \tag{5.1}
\]

We examine in turn each of the three infinite series.

A. The series (A, A)

The models \( (A_{p-1}, A_{q-1}) \), \( p \) odd and \( q \) even, have the symmetry group \( Z_2 \). The invariant boundary conditions \( \alpha = (a, b) \) are controlled by the tadpole graph \( T_{(p-1)/2} \times A_1 \), i.e. \( a \) runs from 1 to \( (p-1)/2 \) and \( b = q/2 \).

The frustrated partition functions are \[ Z_{g,e}(A, A) = \frac{1}{2} \sum_{r,s} \chi_{r,s}^* \chi_{r,q-s} = \sum_{t \leq r \text{ odd} \leq p-1} \chi_{r,s}^* \chi_{r,q-s}, \tag{5.2}
\]
from which it follows that the twisted Ishibashi states \( |j\rangle_g \) can be labelled by

\[ \mathcal{E}_g(A, A) = \{ j = (m, q') : 1 \leq m \text{ odd} \leq p-1 \}. \tag{5.3}
\]
(Which representative \( r, s \) or \( p-r, q-s \) we take does not matter, since the \( S \) matrix elements are the same.)

For these values of \( j \), an easy calculation yields

\[
\frac{S_{i,j}}{S_{1,j}} = (-1)^{(r+1)(q+1)} U_{r-1}(-2 \cos \frac{\pi m}{p}) U_{s-1}(0). \tag{5.4}
\]

Since \( q \) is even, the numbers which appear as arguments of \( U_{r-1} \) coincide with the set \( \{ 1 \} \) of eigenvalues of the incidence matrix \( T_{(p-1)/2} \). A simple comparison with the matrices \( \tilde{n}(g)^i \), as computed from (4.6) and (4.12),

\[
\tilde{n}(g)^i = (-1)^{(r+1)(q+1)} U_{r-1}(T_{\frac{1}{2}}) U_{s-1}(0). \tag{5.5}
\]

shows that the eigenvalues of \( \tilde{n}(g)^i \) are indeed the numbers in \[ \{ 1 \} \] for \( j \in \mathcal{E}_g \).

As mentioned before, the matrices \( n^i \) are the fusion matrices \( N^i \) themselves \[ \{ 1 \} \], equal, from (2.11), to

\[
n^i(a_1, b_2, a_2, b_2) = N^i(a_1, b_2, a_2, b_2) = U_{r-1}(T_{\frac{1}{2}}), \tag{5.6}
\]
for all odd \( s \), and identically equal to zero for \( s \) even. This then leads to

\[
\tilde{n}(g)^i = (-1)^{(r+1)(q+1)} + \frac{1}{q} N^i(a_1, b_2, a_2, b_2). \tag{5.7}
\]

This equation shows clearly that \( \tilde{n}(g)^i \) is compatible with \( n^i \) in the sense explained before.

B. The series (A, D)

All models \( (A_{p-1}, D_{q/2+1}) \), with two coprime integers \( p, q \) and \( p \) odd as before, have also a \( Z_2 \) symmetry. The non–trivial group element \( g \) induces the automorphism \( \sigma \) of \( D_{q/2+1} \) which exchanges the last two nodes. Therefore the symmetric boundary states correspond to the nodes \( (a, b) \) of the fixed point diagram \( T_{(p-1)/2} \times A_{q/2-1} \), pictured in Section II, so that \( a \) is between 1 and \( (p-1)/2 \), and \( b \) is between 1 and \( q/2-1 \).

The eigenvalues of \( T_{(p-1)/2} \) have been recalled earlier, while those of \( A_{q/2-1} \) are well known:

\[
\text{spec}(T_{\frac{1}{2}}) = \{ 2 \cos \frac{\pi m}{p} : 1 \leq m \text{ odd} \leq p-1 \}, \tag{5.8}
\]

\[
\text{spec}(A_{\frac{q}{2}+1}) = \{ 2 \cos \frac{\pi m'}{q} : 1 \leq m' \text{ even} \leq q-1 \}. \tag{5.9}
\]

The frustrated (antiperiodic) partition function on the torus is (the double sums run over \( [1, p-1] \times [1, q-1] \))

\[
Z_{g,e}(A, D) = \sum_{r \text{ odd} \leq p-1 \atop s \text{ even} \mod 2} |\chi_{r,s}|^2 + \sum_{s \text{ odd} \leq q-1 \atop r \text{ even}} \chi_{r,s}^* \chi_{r,q-s}. \tag{5.10}
\]

Thus the Kac labels of the \( g \)–Ishibashi states \( |j\rangle_g \) can be chosen in the set

\[ \mathcal{E}_g(A, D) = \{ j = (m, m') : 1 \leq m \text{ odd} \leq p-1, \]

\[ 1 \leq m' \text{ even} \leq q-1 \}. \tag{5.11}
\]

From this, one computes

\[
\frac{S_{i,j}}{S_{1,j}} = (-1)^{(r+1)} U_{r-1}(-2 \cos \frac{\pi m}{p}) U_{s-1}(-2 \cos \frac{\pi m'}{q}), \tag{5.12}
\]

which coincide, in view of (5.8) and (5.9), with the eigenvalues of

\[
\tilde{n}(g)^i = (-1)^{(r+1)} U_{r-1}(T_{\frac{1}{2}}) U_{s-1}(A_{\frac{q}{2}+1}^{-1}) b_1 b_2. \tag{5.13}
\]
The numbers in the set \( \{ 2 \cos \frac{2\pi m}{q} \} \) come by pairs of opposite sign, so that the set of ratios \((5.12)\), for fixed \( i \), is the same whether or not there is a minus sign in the argument of \( U_{s-1} \). Each individual ratio however differs by a factor \((-1)^{q+1} \), which then leads to an alternative solution \((-1)^{q+1} n^{(g) i} \).

Finally the compatibility of \( \tilde{n}^{(g) i} \) with the original matrices \( n^i \) can be established. In the sector of invariant boundary conditions, the latter read

\[
n^i_{\alpha,\beta} = U_{r-1}(T_{\frac{r-1}{2}}) a_1 a_2 U_{s-1}(D_{\frac{s-1}{2}}) b_1 b_2, \quad (5.14)
\]

where \( b_1, b_2 \) are restricted to lie in \([1, q/2 - 1]\). One may simply notice the following modular identity (same values of the indices)

\[
U_{s-1}(D_{\frac{s-1}{2}}) = U_{s-1}(A_{\frac{s-1}{2}}) \mod 2. \quad (5.15)
\]

It has the immediate consequence that

\[
\tilde{n}^{(g) i}_{\alpha,\beta} = n^i_{\alpha,\beta} \mod 2, \quad (5.16)
\]

which shows the required compatibility.

One may note that all the entries of \( \tilde{n}^{(g) i} \) are in \( \{0, +1, -1\} \), and that those of \( n^i \) are in \( \{0, 1, 2\} \), which implies that all doubled primary fields have opposite \( Z_2 \) charges within each pair.

When \( q = 6 \), i.e. for the \((A_{p-1}, D_4)\) models, \( Z_3 \) invariant boundary conditions can be investigated. They are labelled by nodes \((a, 2)\) with \( a \) in \((p-1)/2\).

The \( Z_3 \) frustrated partition functions on the torus are

\[
Z_{g,e}(A, D_4) = \sum_{r \text{ odd}} |\chi_{r,3}|^2 + \sum_{r \text{ odd}} \chi_{r,3}^2 [\chi_{r,1} + \chi_{r,5}] + \text{c.c.}, \quad (5.17)
\]

so that the Ishibashi states in the \( Z_3 \)-twisted sector have labels \( j = (m, 3) \) for \( m \) odd between 1 and \( p - 1 \).

The matrices \( \tilde{n}^{(g) i} \) in \((5.14)\) can be compared with the restriction of \( n^i \) to the sector of invariant boundary conditions, given by \( U_{r-1}(T_{(p-1)/2}) a_1 a_2 U_{s-1}(D_4)_{2 \text{.2}} \). All matrices are identically zero for \( s \) even, while for \( s \) odd:

\[
n^i = U_{r-1}(T_{\frac{r-1}{2}}) = \tilde{n}^{(g) i}, \quad \text{for} \ s = 1, 5,
\]

\[
n^i = 2U_{r-1}(T_{\frac{r-1}{2}}), \quad \tilde{n}^{(g) i} = -U_{r-1}(T_{\frac{r-1}{2}}), \quad \text{for} \ s = 3. \quad (5.18)
\]

As in the \( Z_2 \) case, the second line shows that the doubled fields have opposite and non-zero \( Z_3 \) charge (if \( \omega \neq 1 \) is a third root of unity, \( \omega + \omega^2 = -1 \)).

C. The series \((A, E_6)\)

The models \((A_{p-1}, E_6)\) are similar to the \((A, D)\) models. In particular the formula for the matrices \( \tilde{n}^{(g) i} \) is the same as for the \((A, D)\) models (with \( A_{q/2-1} \) replaced by \( A_2 \)).

A unique feature of the models based on \( E_6 \) however is that some of the fields occur tripled in some boundary conditions (in addition to some others being doubled). One finds that these are the fields \((r, s)\) with \( s = 5 \) and \( 7 \), in the boundary conditions corresponding to the nodes \((a, 3)\), for \( a \) in \((p-1)/2 \) (with \( b = 3 \) the intersection of the three branches of \( E_6 \)). This follows from the fused adjacency matrices \( U_4(E_6) \) and \( U_6(E_6) \), which, when restricted to the nodes \( b = 3, 6 \) corresponding to the symmetric boundary conditions, read

\[
U_4(E_6) = U_6(E_6) = \begin{pmatrix} 3 & 0 \\ 0 & 1 \end{pmatrix}. \quad (5.19)
\]

VI. UNICITY

The boundary conditions that are invariant under a group element \( g \) correspond to boundary states which have expansions in \( g \)-Ishibashi states \[6.1]\]

\[
| \alpha \rangle = \sum_{c \in E_6} c_\alpha^{(g) i} | i \rangle \quad \text{\( g \)-Ishibashi states}.
\]

The coefficients in \((6.1)\) provide a specific solution \( \tilde{n}^{(g) i} \) to Cardy’s equation \((4.3)\). As for the \( n^i \), one may raise the question of the unicity of this solution.

For every \( g \), the symmetric boundary conditions exhaust the \( g \)-Ishibashi states. It means that every other symmetric boundary state must be a linear combination of those we already have, and so must be one of them. However, since the boundary states \( | \alpha \rangle \) enter Cardy’s formula through scalar products, it is the boundary rays more than the boundary states which matter. Thus the basic question is whether one keeps a sensible solution if one multiplies the boundary states by phases.

Clearly if the symmetric boundary states are multiplied by phases, \( | \alpha \rangle \rightarrow \varphi_\alpha | \alpha \rangle \), the matrices change according to \( \tilde{n}^{(g) i}_{\alpha,\beta} \rightarrow \varphi_\alpha \varphi_\beta^{-1} \tilde{n}^{(g) i}_{\alpha,\beta} \), which satisfy the minimal fusion algebra for any choice of phases.

Whereas for \( g = e \), the positivity of \( n^{(e) i} = n^i \) forces all the phases to be equal, this is no longer the case when \( g \neq e \). Since the matrices \( n^{(g) i} \) are \( \mathbb{Z} \)-valued, the only condition one has is that the phases must be equal up to signs, \( \varphi_\alpha = \epsilon_\alpha \varphi \).

For a \( Z_2 \) symmetry (or subgroup), the new matrices \( \epsilon_\alpha \epsilon_\beta \tilde{n}^{(g) i}_{\alpha,\beta} \) are also solutions of the Cardy equation, because they too are compatible with the \( n^i \). Indeed the compatibility amounts to check that \( n^i \) and \( \tilde{n}^{(g) i} \) coincide modulo 2, which obviously remains true if signs are the same as for the \((A, D)\) models (with \( A_{q/2-1} \) replaced by \( A_2 \)).

The full expansion of \( | \alpha \rangle \) involves Ishibashi states from the \( g \)-twisted bulk sectors for all \( g \) which leave \( \alpha \) invariant.
inserted. Moreover, the identity occurs in the diagonal boundary conditions only, \( \alpha = \beta \), for which the signs cancel out.

On the contrary, in the case of a \( Z_3 \) symmetry, the insertion of signs \( \epsilon_\alpha \) does not yield sensible solutions (as far as the minimal models are concerned). The reason is that some of the fields occur with multiplicity two. Since the corresponding entries in \( n^{(g)} \) must be real combinations of two third roots of unity, they can only be 2 or \(-1\). Therefore, changing their sign by inserting some \( \epsilon_\alpha \) is not consistent.

Thus when the symmetry group is \( Z_2 \), there is a vast number of seemingly acceptable solutions. These various solutions differ by the charges which are assigned to the primary fields in mixed boundary conditions (\( \alpha \neq \beta \)). The freedom we have in choosing the \( \epsilon_\alpha \) reflects the fact that the charge normalization in mixed boundary conditions cannot be fixed a priori, unlike what happens for diagonal boundary conditions, in which an identity occurs.

One may try to derive more constraints on the charge normalizations by requiring that the boundary charge assignments be compatible with (i) the charge assignments in the bulk, and (ii) the boundary field operator product coefficients.

The first requirement is a condition on the way bulk fields close to a boundary (taken to be \( y = 0 \)) expand in boundary fields

\[
\phi_j(x+iy) \sim \sum_{k,c} \sum_{\alpha} \left( 2^k (2y)^{h_k-2h_j} \phi^{\alpha \alpha}_k(x) \right),
\]

where the summation on \( \alpha \) is over all boundary conditions, not just the invariant ones. The \( Z_2 \) symmetry implies selection rules on the coefficients since a bulk field of a given parity should expand in a combination of boundary fields that transforms the same way. It means that the parity of the field \( \phi^{\alpha \alpha}_k \) must match that of \( \phi_j \) for all invariant boundary conditions \( \alpha \) such that \( (\alpha)B_j \neq 0 \).

Since these expansions involve fields in diagonal boundary conditions only, the selection rules that follow are the same no matter what the signs \( \epsilon_\alpha \) are. This does not prove however that the selection rules are indeed satisfied. For the diagonal models \((A,A)\), the coefficients \( (\alpha)B_j \) are known explicitly \([14]\), and it would be interesting to check directly that their values are consistent with the boundary charge assignment found here.

The second check concerns the operator algebra of the boundary fields themselves

\[
\phi^{\alpha \beta}_i(x) \phi^{\beta \gamma}_j(x') \sim \sum_k c^{(\alpha \beta \gamma)}_{ij} k(x-x')^{h_k-h_i-h_j} \phi^{\alpha \gamma}_k(x').
\]

Restricting to invariant boundary conditions \( \alpha, \beta, \gamma \), the discrete symmetry implies again selection rules which require that the charges given by the matrices \( n^{(g)} \rightarrow \) provide a grading of the boundary fusion algebra

\[
C^{(\alpha \beta \gamma)}_{ij} k \neq 0 \implies n^{(g)}_{\alpha,\beta} n^{(g)}_{\beta,\gamma} = n^{(g)}_{\alpha,\gamma}. \quad (6.4)
\]

It is obvious that if the matrix coefficients \( n^{(g)}_{\alpha,\beta} \) satisfy \([14]\), the same will be true of \( \epsilon_\alpha \epsilon_\beta n^{(g)}_{\alpha,\beta} \), so that here too, these matrices are all consistent with the boundary operator product expansion \([6.3]\), or else none of them is. As the discrete symmetry is expected to occur, one can be confident in the fact that the selection rules will be satisfied. We give below examples of selection rules in the most explicit case, namely the diagonal models. We have not shown in general that they are indeed satisfied, and as before, a proof not based on symmetry arguments would be valuable.

In the diagonal models \((A,A)\), the boundary conditions are in one–to–one correspondence with the chiral primary fields through their labelling by two nodes \((a,b)\) taken in \( A_{p-1} \) and \( A_{q-1} \). As before, the boundary conditions \((a^*,b^*) = (p - a, q - b)\) and \((a,b)\) are to be identified. Without loss of generality, one may thus assume that the first label (the "\( i\)-label") is odd.

The boundary operator product coefficients are known explicitly from \([15]\), where they were proved to be equal to coefficients of the crossing matrices (in a suitable normalization)

\[
C^{(\alpha \beta \gamma)}_{ij} k = F_{\beta,k} \left( \begin{array}{c} \alpha \\ i \\ \gamma \end{array} \right). \quad (6.5)
\]

Since for instance, an odd boundary field \( \phi^{\alpha \alpha}_i \) cannot occur in its fusion with itself, the corresponding crossing coefficient must vanish. The verification that it does is non–trivial only when the chiral field \( i \) indeed occurs in its own bulk fusion (namely \( N_{ii}^{(g)} \neq 0 \)), when the primary field \( i \) indeed occurs in the diagonal boundary conditions \( (n_{\alpha,\alpha} \neq 0 \) for \( \alpha \) invariant under \( Z_2 \)), and when it is an odd field \( (n_{\alpha,\alpha}^{(g)} = -1) \). All three conditions can be easily worked out, and yield

\[
F_{\alpha,i} \left( \begin{array}{c} \alpha \\ i \\ \alpha \end{array} \right) = 0 \quad (6.6)
\]

for all \( i = (r,s) \) such that \( r, s \) are odd, \( s = 3 \mod 4 \), \( r \leq (2p - 1)/3 \), \( s \leq (2q - 1)/3 \), and for all \( \alpha = (a,q/2) \) such that \( (r + 1)/2 \leq a \leq p/2 \).

The simplest example where such constraints arise is the tetracritical Ising model \((A_4,A_5)\), in which \( 6.6 \) implies (in terms of conformal weights)

\[\text{We leave aside the cases where some matrix elements } n^{(g)}_{\alpha,\beta} \text{ are zero without having the corresponding elements in } n^{(g)}_{\alpha,\beta} \text{ equal to zero. This happens when primary fields come in pairs of opposite charge.}\]

8
More conditions can be derived in a generic diagonal model.

To summarize, the matrices $\tilde{n}^{(g)i}$ displayed in (4.4) and [4.12] yield but a particular solution to Cardy’s equation. For a $Z_3$ symmetry, they form the only consistent solution,

$$n^{(g)i}_{\alpha,\beta} = \tilde{n}^{(g)i}_{\alpha,\beta}, \quad (g^3 = e), \tag{6.8}$$

whereas, in the case of a $Z_2$ symmetry, there are many more given by

$$n^{(g)i}_{\alpha,\beta} = \epsilon_\alpha \epsilon_\beta \tilde{n}^{(g)i}_{\alpha,\beta}, \quad \epsilon_\alpha = \pm 1 \quad (g^2 = e), \tag{6.9}$$

for arbitrary signs. The effect of these signs is to reverse (or to maintain, depending to the value of $\epsilon_\alpha \epsilon_\beta$) the parity of all the fields that occur in the sector of boundary conditions $\alpha, \beta$.

The ambiguity in the normalization of the $Z_2$ charges that arises due to these signs must be resolved on physical grounds. As the interpretation of the boundary fields is lacking in the general non–unitary model, it is not clear to the author what the correct requirement should be. In this context, the specific choice $\epsilon_\alpha = +1$ for all $\alpha$ is a minimal and natural one, as it extends nicely the graph theoretic description. It also has the distinctive feature of producing matrices $\tilde{n}^{(g)i}$ of constant sign, either totally positive or totally negative. However in view of what follows, this may not be the correct choice.

In a unitary model, the ground state of every sector is expected to be invariant under the symmetry group, on account of the Perron–Frobenius theorem applied to the transfer matrix. This provides a well–defined criterion to fix the normalization of the charges, and therefore the physical value of the signs $\epsilon_\alpha$. We will use this criterion as a guide, in order to see if a particular set of values $\epsilon_\alpha$ emerges from this point of view.

### VII. UNITARY MODELS

In this last section, we explore the possibility of fixing the value of the signs $\epsilon_\alpha$ by using the criterion we have just mentioned: if the continuum limit is smooth enough, it is expected that the consequences of the Perron–Frobenius theorem on the finite–dimensional transfer matrix be maintained in the corresponding conformal field theory. In particular, for all invariant boundary conditions, the ground state of the Hamiltonian $H_{\alpha,\beta}$ (the primary field of lowest conformal dimension in $\mathcal{H}_{\alpha,\beta}$) should be non–degenerate and (hence) invariant under the symmetry group. In short, we will call this the Perron–Frobenius (PF) criterion. As already said, it is automatically satisfied in the diagonal boundary conditions.

Thus we look for a set of $\epsilon_\alpha$ such that the $Z_2$ charge assignment meet the PF criterion. Incidentally, when the symmetry group is $Z_3$, there is only one consistent charge assignment (see the previous section). In that case, we will merely check whether the PF criterion is satisfied.

The outcome of this investigation is somewhat surprising. The unitary diagonal models are the only ones where the PF criterion can be met, for a unique choice of the $\epsilon_\alpha$’s. In all other unitary models, there is no way in which it can be fulfilled, if one insists that it be valid in all sectors. A physical interpretation of this will be proposed.

Nonetheless, for all those models but two, we will see that a unique set of $\epsilon_\alpha$’s is singled out by demanding a minimal violation of the PF criterion.

We recall that the conformal weight of a primary field labelled by $i = (r, s)$ is equal to

$$h_{r, s} = (qr - ps)^2 - (p - q)^2, \tag{7.1}$$

Throughout this section, we will take $p$ odd and $q = p \pm 1$ even. Then the smallest conformal weights correspond, in ascending order, to $i = (1, 1), (2, 2), (3, 3), \ldots$. 

### A. The unitary series (A,A)

The only boundary primary fields that occur in the diagonal models have their $s$-label odd (see (7.1)). Since the identity $(1,1)$ does not appear in mixed boundary conditions, the primary with the lowest weight that can possibly occur in mixed boundary conditions corresponds to $(3,3)$, and consequently, the off–diagonal entries of

$$n^{(g)(3,3)}_{\alpha,\beta} = n^{(g)(3,3)}_{\alpha_1,\beta_1}, n^{(g)(3,3)}_{\alpha_2,\beta_2} = -\epsilon_{\alpha_1} \epsilon_{\alpha_2} U_2(T_{\pm 1})_{\alpha_1,\alpha_2} \tag{7.2}$$

must be positive. The off–diagonal matrix coefficients $U_2(T)_{\alpha_1,\alpha_2}$ equal 1 if $|\alpha_1 - \alpha_2| = 2$ or if $\{\alpha_1, \alpha_2\} = \{(p -

---

7There is another solution in terms of matrices of constant sign, which is obtained by substituting $-G^n$ for $G^n$ in the formula (4.4) giving $\tilde{g}^{(g)i}$. The substitution has no effect when $G^n = A_1$, since the associated adjacency matrix is the number zero, while in the other cases, it causes the matrices $\tilde{g}^{(g)i}$ to be multiplied by $(−1)^{s+1}$. This sign can be seen to be in the line of the previous discussion, because it is equal to $(-1)^{s+1} = \epsilon_\alpha \epsilon_\beta$ with $\epsilon_\alpha = (-1)^{s+1}$ if $\alpha = (a, b)$.

8I am indebted to Gerard Watts for a clarifying discussion about this issue.
3)/2, (p − 1)/2), and 0 otherwise (it counts the number of paths of length 2 going from \(a_1\) to \(a_2\) on the graph \(T_{(p−1)/2}\)). Thus one obtains the condition \(\epsilon_{a_1, a_2} = −1\) for all these pairs. This fixes the vector \(\epsilon_a\) in a unique way (up to a global sign that does not matter) as

\[
\epsilon_a = (\ldots, +1, +1, −1, −1, +1, +1, −1, −1, +1). \tag{7.3}
\]

For these specific signs, one may then verify that in the remaining mixed boundary sectors (those for which (3,3) does not occur), the field of lowest weight has indeed a parity +1 (zero charge). To do that, one can first observe that any mixed boundary sector has its field of lowest weight in \(\{(r, s) : 3 \leq r = s \text{ odd} \leq p − 2\}\). Next point is to note that \(U_{r−1}(T)_{a_1, a_2}\) is zero unless the nodes \(a_1, a_2\) can be related by a path of length \(r − 1\). If the two nodes cannot be connected by a shorter path, it follows from (7.3) that \(\epsilon_{a_1, a_2} = (−1)^{(r−1)/2}\), so that the numbers

\[
n^{(g)}_{(a_1, \frac{q}{2}), (a_2, \frac{q}{2})} = \epsilon_{a_1, a_2} (−1)^{(r−1)/2} U_{r−1}(T)_{a_1, a_2} \tag{7.4}
\]

are positive (or zero). That \(a_1\) and \(a_2\) can be connected by a shorter path means that the field \((r, r)\) is not the primary with the lowest weight in that sector, and we are back to the first case.

Since the PF criterion can be satisfied in all sectors for a unique set of \(\epsilon_a\)’s, it is tempting to conjecture that these are the correct physical values. The charge content in the various sectors of the unitary diagonal models would then be given by

\[
n_{(a_1, \frac{q}{2}), (a_2, \frac{q}{2})} = \epsilon_{a_1, a_2} n^{(g)}_{(a_1, \frac{q}{2}), (a_2, \frac{q}{2})}, \tag{7.5}
\]

with the signs (7.4), and the \(n^{(g)}\) as in (5.7).

B. The unitary series (A,D)

The same calculations can be carried out for the unitary models of the (A, D) series, with however different results. To illustrate it most clearly, we will start with the simplest case, namely \((A_4, D_4)\), corresponding to the critical 3–Potts model \((p = 5, q = 6)\).

A set of \(Z_2\)–symmetric boundary conditions is provided by the so-called A, BC, Free and New. They correspond respectively to the nodes \((1, 1)\), \((2, 1)\), \((1, 2)\) and \((2, 2)\). (Free and New, being fully invariant under \(S_3\), must correspond to \(b = 2\), which is the only node of \(D_4\) invariant under \(S_3\).) Together they define 10 different sectors.

It is not difficult to find the field with lowest weight in each of these sectors, and then compute the parity they are assigned by the matrices \(\hat{M}^{(g)}\) computed in Section 3. Writing these in a matrix \(\hat{M}\), one obtains (indices are A, BC, Free, New)

\[
\hat{M}_{\alpha, \beta} = \left(\hat{M}^{(g)}\right)_{\alpha, \beta} = \left(\begin{array}{cccc}
+1 & +1 & +1 & +1 \\
−1 & +1 & −1 & −1 \\
+1 & +1 & −1 & 0 \\
−1 & −1 & 0 & +1
\end{array}\right). \tag{7.6}
\]

The zeros are due to the partition function (superscripts are the conformal weights)

\[
Z_{\text{Free,New}} = 2 \chi_{3,3}^{1/15} + 2 \chi_{3,5}^{2/5} + \chi_{3,1}^{7/5}, \tag{7.7}
\]

which shows that the ground state in that sector is doubly degenerate, the two states having opposite parities.

The above matrix makes clear that the charge assignment implied by \(\hat{M}^{(g)}\) does not satisfy the PF criterion in all sectors, either because the ground state is not invariant, or because it is degenerate. One may try to find values for \(\epsilon_a\) that render the non–degenerate ground states invariant, but one easily sees that it is not possible: no values for \(\epsilon_a\) can be found so that \(\hat{M}_{\alpha, \beta} \geq 0\) for all \(\alpha, \beta\).

One can relax our demands by looking for a set of \(\epsilon_a\) which minimizes the number of sectors that violate the PF criterion. One then finds that the minimal number of such sectors, which we call non–PF, is equal to

\[
N_{\text{non–PF}} = 2. \tag{7.8}
\]

This number is realized for \(\epsilon_a = (+1, −1, +1, −1) \otimes (1, 1)_b\), the two non–PF sectors being BC,New and Free,New. Indeed for these \(\epsilon_a\), one obtains

\[
\epsilon_a \epsilon_{\beta} \hat{M}_{\alpha, \beta} = \left(\begin{array}{cccc}
+1 & +1 & +1 & +1 \\
+1 & +1 & +1 & −1 \\
+1 & +1 & +1 & 0 \\
+1 & −1 & 0 & +1
\end{array}\right). \tag{7.9}
\]

Let us also notice that if one excludes just one boundary condition, namely “New”, the expected consequences of the PF theorem are indeed verified. Thus in this case, the minimal number of boundary conditions that have to be excluded for this to be true is equal to 1.

Finally one may note that \(\epsilon_a = (+1, −1, +1, +1)\) share the same properties, the two non–PF sectors being now A,New and Free,New.

In any case, one must conclude that the transfer matrix, in certain sectors of boundary conditions, does not satisfy the conditions of the PF theorem. There can be only two reasons for that: either the transfer matrix is
not irreducible\textsuperscript{\textordmasculine} or else it contains negative entries, implying that some of the boundary Boltzmann weights are negative (or both).

That the first condition fails is unlikely because the periodic transfer matrix is irreducible and because the boundary conditions are undecomposable. So one should favour the second alternative, which points to the unphysical nature of some of the boundary conditions, their classical description requiring negative Boltzmann weights. We note that a boundary condition \( \alpha \) which is described by negative Boltzmann weights does not necessarily lead to unphysical (negative, non–PF) partition functions. Whether or not this is the case depends on which other boundary condition is associated with \( \alpha \).

The appearance of negative classical boundary Boltzmann weights to describe the New boundary condition in the critical 3–Potts model has been discussed in \[7\], and is confirmed by the explicit calculation of the critical boundary weights \[7\].

As we shall see, what is true in the 3–Potts model is true in all unitary models of the \((A, D)\) series. No values for the \( \epsilon_{\alpha} \)’s exist which make all sectors to satisfy the PF criterion, but a suitable choice, unique, contrary to the above case, of \( \epsilon_{\alpha} \) minimizes the number of sectors which do not satisfy it. As above we will take the point of view that these features are the signal that a certain number of boundary conditions are unphysical, because they require negative Boltzmann weights for their classical description.

We have not carried out the analysis of the whole series, but instead we have investigated the first eight models, up to \( p = 13 \) and \( q = 12 \), with the following results.

In each of these models, we have determined the minimal number \( N_{\text{unphys}} \) of boundary conditions that must be disregarded in order to satisfy the PF criterion in all the sectors involving the remaining ones. This uniquely singles out a set of boundary conditions, which naturally qualifies as the set of unphysical boundary conditions. This also determines unique values of the \( \epsilon_{\alpha} \) for the physical ones. The values of \( \epsilon_{\alpha} \) for the unphysical \( \alpha \) are then fixed (uniquely, except in the 3–Potts model) by requiring a minimal number of non–PF sectors (which necessarily correspond to one or two unphysical boundary conditions). That minimal number is denoted by \( N_{\text{non–PF}} \). The results are as follows.

In the models \((A_{p−1}, D_{q/2+1})\) (we have looked at the eight models corresponding to \( 6 \leq q \leq 12 \)), the number \( N_{\text{unphys}}(p, q) \) only depends on the rank of the \( D \) factor. It increases rather quickly since it is equal to 1, 3, 6 and 10 for the two models involving the algebra \( D_4, D_5, D_6 \) and \( D_7 \) respectively. We found that the unphysical boundary conditions form the set (the labelling of the nodes is as in the figure of Section \[11\])

\[
\{ \alpha = (a, b) \in T_{p−1} \times A_{q/2−1} : a + b \geq \frac{p+3}{2} \}.
\] (7.10)

Moreover, the signs which make the number of non–PF sectors minimal are unique and given by

\[
\epsilon_{\alpha} = (+1, −1, +1, −1, \ldots) a \otimes (1, 1, 1, \ldots) b = (-1)^{a+1}, \quad \alpha = (a, b).
\] (7.11)

As pointed out above, in the model \((A_4, D_4)\), there is another solution \( \epsilon_{\alpha} = (+1, −1, +1, +1) \), which however appears to contradict the duality relations (see below).

We have determined \( N_{\text{non–PF}} \) by mere counting, and found that it equals 2, 3, 11, 15, 36, 46, 89, 109 for the first eight models, ordered as \((A_4, D_4), (A_6, D_4), (A_6, D_5), \ldots \) (By symmetry, the sectors \((\alpha, \beta)\) and \((\beta, \alpha)\) are identical and count for one.)

These results strongly suggest the general pattern in which the number of boundary conditions in (7.10) equals a binomial coefficient

\[
N_{\text{unphys}}(A, D_{\frac{q}{2}+1}) = \binom{\frac{q}{2} − 1}{2}.
\] (7.12)

This is a large number since essentially half the invariant boundary conditions would have to be discarded as classically unphysical. A bit more of numerology also shows that the number of non–PF sectors fits the simple formula

\[
N_{\text{non–PF}}(A_{q−1−1}, D_{\frac{q}{2}+1}) = \{(Z_2^2)^4 + 2(q−2)(q+2)(q−4)\}/192,
\] (7.13)

where \( \{x\} \) is the integer closest to \( x \). The two numbers in the r.h.s. of the previous equation have separately a well-defined meaning: the first one is the number of sectors where the ground state is non–degenerate but odd under the \( Z_2 \) symmetry, while the second one gives the number of sectors where the ground state is doubly degenerate.

The reader may wish to check the above assertions in a less simple instance than the Potts model. A good example is to consider the \((A_6, D_3)\) model, for which one computes (in the tensor product basis)

\[
\tilde{M}_{\alpha, \beta} = \begin{pmatrix}
+1 & −1 & +1 & +1 & −1 & −1 & +1 & −1 \\
−1 & +1 & −1 & +1 & −1 & +1 & −1 & +1 \\
+1 & −1 & +1 & +1 & −1 & −1 & +1 & +1 \\
−1 & +1 & +1 & −1 & +1 & −1 & +1 & +1 \\
+1 & −1 & −1 & −1 & +1 & +1 & −1 & +1 \\
+1 & +1 & −1 & +1 & +1 & +1 & −1 & +1 \\
−1 & +1 & −1 & −1 & 0 & 0 & +1 & +1 \\
−1 & +1 & −1 & −1 & 0 & 0 & +1 & +1
\end{pmatrix}.
\] (7.14)

The values of \( \epsilon_{\alpha} \) mentioned in (7.11) are nothing but the first line of \( \tilde{M}_{\alpha, \beta} \) and the boundary conditions to discard label the rows and columns 6, 8 and 9, which

\textsuperscript{\textordmasculine} The unicity of the largest eigenvalue is guaranteed only for non–negative primitive matrices \[14\]. Under mild assumptions on the transfer matrix, its irreducibility is sufficient.
correspond, in terms of the fixed point graph $T_3 \times A_3$, to the pairs of nodes $(a, b) = (3, 2), (2, 3)$ and $(3, 3)$, as announced in (7.11). There are 6 zeros in the upper triangular part of $M_{\alpha, \beta}$, which is the value of the second summand of (7.13).

All this leads to the reasonable guess that (7.11) might give the correct physical values of the $\epsilon_\alpha$'s. Inserted in (6.9), it not only determines the parities of all primaries in the sectors where the PF criterion is satisfied, but it also points to the boundary conditions that can have a problematic lattice interpretation. These conjectural statements must be confirmed or dismissed by the explicit calculation of the boundary Boltzmann weights. The results obtained so far seem to give some support to our conjecture [18].

Assuming this conjecture, it is not difficult to give an explicit formula for the parities. From (4.6), (4.12) and (7.11), they are determined from

$$n_{(a_1,b_1),(a_2,b_2)}^{(g)i} = (-1)^{a_1+a_2+r+1} \times U_{r-1}(T_{(p-1)})_{a_1a_2} U_{s-1}(A_{q-1})_{b_1b_2}. \quad (7.15)$$

The matrices $U_{r-1}(T_{(p-1)/2})$ are all positive, unlike the $U_{s-1}(A_{q-2-1})$, which are positive for $s < q/2$, negative for $s > q/2$, and identically zero for $s = q/2$, on account of $U_{q-s-1}(A_{q-2-1}) = -U_{s-1}(A_{q-2-1})$.

Putting all these observations together, one can conclude that the paired fields have opposite $Z_2$ parities within each pair (as already pointed out), and that the parity of an unpaired field in the sector of boundary conditions $\alpha, \beta$ is equal to

$$g(\phi_i^{\alpha\beta}) = \begin{cases} (-1)^{a_1+a_2+r+1} \phi_i^{\alpha\beta} & \text{if } s < q/2, \\ (-1)^{a_1+a_2+r} \phi_i^{\alpha\beta} & \text{if } s > q/2. \end{cases} \quad (7.16)$$

In the critical 3–Potts model for instance, one finds the following frustrated partition functions (in terms of the conformal weights)

$$Z^g_{A,A} = \chi_0 - \chi_3, \quad (7.17)$$

$$Z^g_{A,BC} = \chi_2/5 - \chi_7/5, \quad (7.18)$$

$$Z^g_{BC,Free} = \chi_1/8 - \chi_3/8, \quad (7.19)$$

$$Z^g_{BC,BCE} = \chi_0 - \chi_3 - \chi_2/5 + \chi_7/5, \quad (7.20)$$

$$Z^g_{BC,BC} = \chi_0 - \chi_3 + \chi_2/3 - \chi_2/3^+, \quad (7.21)$$

$$Z^g_{BC,Free,Free} = \chi_0 - \chi_3 + \chi_2/3 - \chi_2/3^+, \quad (7.22)$$

$$Z^g_{A,New} = \chi_1/40 - \chi_3/21/40, \quad (7.23)$$

$$Z^g_{BC,New} = \chi_0 - \chi_3 - \chi_2/5 + \chi_7/5 + \chi_2/3 - \chi_2/3^+ + \chi_1/15 - \chi_1/15^+. \quad (7.24)$$

These functions are computed using the $\epsilon_\alpha$'s given in (7.11), and appear to be consistent with the duality of the model [18]. For instance, the equality

$$Z_{BC,Free} = Z_{A,New} \quad (7.25)$$

is maintained for the frustrated partition functions, while

$$Z_{Free,Free} = Z_{A,A} + Z_{A,B} + Z_{A,C} \quad (7.26)$$

becomes $Z_{Free,Free}^g = Z_{A,A}^g$ since $Z_{A,B}^g = Z_{A,C}^g = 0$.

The use of the other solution $\epsilon_\alpha = (+1, -1, +1, +1)$ has the effect of multiplying by $-1$ the partition functions of all sectors with one “New”, so that $Z^g_{A,New}$ would be minus the expression in (7.23), contradicting the duality relation (7.25).

There is a $Z_3$ symmetry in two models only, namely the critical and tricritical 3–Potts models ($A_4, D_4$) and ($A_6, D_4$). They possess respectively 2 (“Free” and “New”) and 3 invariant boundary conditions, namely $\alpha = (a, 2)$ for a $a$ a node of $T_2$ and $T_3$. The relevant $M$ matrices are equal to

$$\tilde{M}_{\alpha, \beta} = \begin{pmatrix} +1 & -1 & +1 \\ -1 & -1 & +1 \end{pmatrix} \quad \text{and} \quad \begin{pmatrix} +1 & +1 & -1 \\ +1 & -1 & -1 \\ -1 & -1 & +1 \end{pmatrix}, \quad (7.27)$$

where a $-1$ sign indicates that the corresponding sector has two degenerate ground states, of opposite and non–zero charge (none of them is invariant under the $Z_3$).

In the first case (the ($A_4, D_4$) model), it is the second boundary condition (2, 2) (i.e. “New”) that appears to be unphysical, while in the second case, it is the third boundary condition (3, 2). This should not be surprising since they are precisely the boundary conditions which were unphysical from the $Z_2$ point of view: from (7.10), $\alpha = (a, 2)$ was to be discarded if $a + 2 \geq (p + 3)/2$, that is, if $a = (p - 1)/2$. Therefore, the boundary conditions which were causing problems for the $Z_2$ charges also cause problems for the $Z_3$ charges.

C. The unitary models ($A_6, E_6$)

We will content ourselves with making a few comments on the two unitary models ($A_{10}, E_6$) and ($A_{12}, E_6$) ($p = 11$ or 13, and $q = 12$).

As we have said above, the models involving the $E_6$ algebra have the peculiarity of possessing primary fields that occur with multiplicity 1, 2 and 3. It turns out that the same is true of the ground state in various sectors. Let us examine in some detail the simplest model ($A_{10}, E_6$).

That model possesses 10 invariant boundary conditions, labelled as $\alpha = (a, b)$ with $a = 1, 2, \ldots, 5$ a node of $T_5$, and $b = 3, 6$ a node of the $A_2$ subgraph of $E_6$, fixed by its non–trivial automorphism. One can compute as before the matrix $\tilde{M}_{\alpha, \beta}$ which collects those entries of $\tilde{n}_{(g)i}^{(a,\beta)}$ for which $i$ is the lowest weight primary in the sector $\alpha, \beta$. The result is

$$\tilde{M}_{\alpha, \beta} =$$
where the stars mean that the ground state in the corresponding sector is three times degenerate, the number ±1 being the sum of the three parities. As before, a zero indicates that there are two degenerate ground states with opposite parity.

We can repeat what we did for the \((A, D)\) series, and look for a set of \(\epsilon_a\) which minimizes the violation of the PF criterion.

By varying the \(\epsilon_a\), one finds that the minimal number of non–PF sectors is equal to 21, and that the non–PF sectors have at least one boundary condition in the set

\[ \{(2, 3), (3, 3), (4, 3), (5, 3), (5, 6)\} \]  

(7.29)

in terms of the nodes of \(T_5 \times A_2\) (they correspond to the rows and columns 2, 3, 4, 5, 10). So these five boundary conditions can presumably be called unphysical in the sense of the previous subsection. Hence

\[ N_{\text{unphys}}(A_{10}, E_0) = 5, \quad N_{\text{non–PF}}(A_{10}, E_0) = 21. \]  

(7.30)

There are four solutions for the \(\epsilon_a\)’s for which these values can be realized. Among them, the most symmetrical one is \(\epsilon_a = (+1, -1, -1, +1, -1) \otimes (1, 1)\).

The other model \((A_{12}, E_0)\) is similar. One finds

\[ N_{\text{unphys}}(A_{12}, E_0) = 5, \quad N_{\text{non–PF}}(A_{12}, E_0) = 27. \]  

(7.31)

The presumably unphysical boundary conditions correspond to the nodes (3,3), (4,3), (5,3), (6,3), (6,6) of \(T_6 \times A_2\). The signs for which these numbers are reached are unique and given by \(\epsilon_a = (+1, -1, +1, +1, -1, +1) \otimes (1, 1)\).

ACKNOWLEDGMENTS

It is a pleasure to thank Jean-Bernard Zuber for an encouraging and stimulating exchange, and for reading the manuscript. I also wish to thank Paul Pearce who has informed me of the preliminary results that he and his collaborators have obtained on boundary Boltzmann weights, Ingo Runkel for pointing out misprints in the draft, and Gerard Watts for a very fruitful discussion.
