Abstract. The mass composition of ultra-high-energy cosmic rays plays a key role in the understanding of the origins of these rare particles. A composition-sensitive observable is the atmospheric depth at which the air shower reaches the maximum number of particles ($X_{\text{max}}$). The Auger Engineering Radio Array (AERA) detects the radio emission in the 30-80 MHz frequency band from extensive air showers with energies larger than $10^{17}$ eV. It consists of more than 150 autonomous radio stations covering an area of about 17 km$^2$. From the distribution of signals measured by the antennas, it is possible to estimate $X_{\text{max}}$. In this contribution three independent methods for the estimation of $X_{\text{max}}$ will be presented.

1 Introduction

The dominant contribution to the radio emission from extensive air shower is the geomagnetic radiation. It is produced by the deflection of electrons and positrons in the Earth’s magnetic field ($\mathbf{B}$) and it is polarized in the direction of the Lorentz force ($\mathbf{v} \times \mathbf{B}$, where $\mathbf{v}$ is the shower axis). A second order contribution comes from a negative charge excess in the shower front: it is called charge excess or Askaryan effect and its radiation is radially polarized towards the shower axis. The superposition of the geomagnetic and charge-excess radiation results in an asymmetric energy density footprint in the shower plane ($\mathbf{v} \times \mathbf{B}$, $\mathbf{v} \times \mathbf{v} \times \mathbf{B}$).

The shower observable related to the mass of the primary particle is the atmospheric depth where the shower reaches the maximum number of charged particles ($X_{\text{max}}$). Several features of the radio signal are used to estimate $X_{\text{max}}$: the energy density distribution at ground level; the shape of the frequency spectrum of each individual antenna; the arrival time distribution of the signal at each antenna. In the following sections the three different methods are described.

2 $X_{\text{max}}$ from the radio energy distribution in the shower plane

Two different parameterization functions for the radio energy density distribution have been tested on CoReas simulations [1] and AERA datasets.

The asymmetric energy density footprint can be described analytically by an empirical function consisting of the subtraction of two two-dimensional Gaussian distributions \([2]\). A linear correlation between the width of the footprint and the geometrical distance to \(X_{\text{max}}\) has been found using CoReas iron and proton simulations with zenith angles up to 55°. The measured noise is included in the simulation along with the full detector response. The uncertainty on the reconstruction is obtained by comparing \(X_{\text{max}}\) to the corresponding Monte Carlo value and is found to be is 51 g cm\(^{-2}\).

The second model, detailed in Ref. \([3]\), uses an analytical description of the geomagnetic and of the charge excess radiation. The parameters of the function are related to physics quantities, such as the radius and the width of the Cherenkov ring which are correlated with the distance to \(X_{\text{max}}\). The uncertainty on the \(X_{\text{max}}\) reconstruction obtained using the same CoReas simulation sample as before improves to 41 g cm\(^{-2}\).

Fig. (1) shows an example of the fit to the energy density for an AERA event. The fit function used in the plot on the left is the subtraction of the two Gaussian distributions, while on the right the geomagnetic and charge-excess parameterization is used. The reconstructed \(X_{\text{max}}^{\text{RD}}\) are compatible with the \(X_{\text{max}}^{\text{FD}}\) measured using the Auger fluorescence telescopes (FD).

Another method was developed in Ref. \([4]\) and later adapted to AERA data. \(X_{\text{max}}\) is obtained by evaluating the agreement of measured radio footprint to air-shower simulations of different \(X_{\text{max}}\) \([5, 6]\).

## 3 \(X_{\text{max}}\) from spectral information

A cosmic ray with a lighter mass produces a longer radio pulse compared to heavier primary particles. In the frequency domain a longer pulse results in a steeper spectrum. Therefore the spectral index \((b)\) of the frequency spectrum contains information on \(X_{\text{max}}\). Using simulations, \(b\) has been parameterized as a function of the arrival direction, the distance antenna-shower axis and the distance to \(X_{\text{max}}\) \([7]\).

The parameterization is valid for zenith angles up to 60° and in the coherent region of the shower outside the Cherenkov cone. Fig. (2) on the left shows a comparison between the spectral index \(b\) as function of the distance antenna-shower axis predicted using \(X_{\text{max}}\) measured by the fluorescence

![Figure 1](image-url)
telescopes and the spectral index measured by each radio antenna. The radio measurement of each antenna is in agreement with the FD prediction. This method proves that even a single antenna is sensitive to $X_{\text{max}}$.

4 $X_{\text{max}}$ from the arrival time distribution

The radio wavefront is well described by a hyperboloid. For distances to the shower axis larger than 50 m, the hyperbola can be approximated with a cone and the cone opening angle ($\rho$) is correlated to the geometrical distance to $X_{\text{max}}$ ($L_{\text{max}}$) [8]. Fig. (2) on the right shows $L_{\text{max}}$ as a function of the cone opening angle $\rho$ for a simulated dataset. The study has been performed using proton primaries with energies ranging from 0.28 EeV to 1 EeV and zenith angles up to 50$^\circ$.

5 Conclusions

Three independent techniques for $X_{\text{max}}$ reconstruction based on the radio signal features are currently studied by the Auger collaboration and show promising results. The results of these analyses could be combined to obtain a mass composition reconstruction that uses all the information in the detected radio signal providing a promising technique for the measurement of $X_{\text{max}}$.
