ABSTRACT

Dynamical studies of superbubbles and Wolf-Rayet ring nebulae show discrepancies from the standard adiabatic model for windblown bubbles. We therefore study the physical properties and kinematics of three candidate bubbles blown by single O stars to evaluate whether these discrepancies are also found in these simpler objects. Our sample candidates are N44 F, N44 J, and N44 M, in the outskirts of the H II complex N44 in the Large Magellanic Cloud. We have obtained ground-based and Hubble Space Telescope emission-line images and high-dispersion echelle spectra for these objects. From the Hα luminosities and the [O III]/Hα ratios of these nebulae, we estimate the spectral types of the ionizing stars to be O7 V, O9.5 V, and O9.5 V for N44 F, N44 J, and N44 M, respectively. We find that the observed expansion velocity of 12 km s⁻¹ for N44 F is consistent with the stellar wind luminosity expected from the central ionizing star, as predicted by the standard bubble model. The observed upper limits for the expansion velocities of N44 J and N44 M are also compatible with the expected values, within the uncertainties. We also report the discovery in N44 F of strongly defined dust columns, similar to those seen in the Eagle Nebula. The photoevaporation of these dense dust features may be kinematically important and may actually govern the evolution of the shell. The inclusion of photoevaporation processes may thus undermine the apparent agreement between the observed bubble dynamics and the simple adiabatic models.

Key words: H II regions — ISM: bubbles — ISM: individual (N44) — ISM: kinematics and dynamics — Magellanic Clouds

1. INTRODUCTION

Mechanical feedback from massive stars is a fundamental driver of galaxy evolution. The supernovae (SNe) and supersonic stellar winds from these stars generate bubbles and shells in the interstellar medium (ISM), which may dominate the ISM structure formation in many star-forming galaxies. The standard adiabatic model for these shells and superbubbles (e.g., Weaver et al. 1977) predicts the production of hot, 10⁶–10⁷ K, low-density gas within these shells, which bear the products of SN and massive star nucleosynthesis. Therefore, these bubble structures are thought to be the source of the diffuse, hot ionized component of the ISM. Vigorous star-forming regions may generate supergiant shells that blow out of galaxy disks, thereby dispersing metals and mass far from the parent star formation event. In addition, this mechanical energy contributes to ISM kinematics and is thought to be a primary source of turbulence (e.g., Norman & Ferrara 1996; Goldman 2000).

The effects of mechanical feedback have been clearly demonstrated, for example, almost all clean examples of bubbles blown by Wolf-Rayet stars and of superbubbles present shells that are too small for their observed parent stellar population (e.g., Treffers & Chu 1982; Drissen et al. 1995). Many superbubbles also show anomalous kinematics and X-ray emission (e.g., Rosado et al. 1982; Chu & Mac Low 1990; Wang & Helfand 1991). To resolve these puzzles and more clearly understand the mechanical feedback process, it is therefore necessary to examine simpler systems.

In active star-forming regions, high concentrations of OB stars collectively produce superbubbles. But in their peripheries, where stars are loosely distributed, discrete bubbles may be produced by individual stars. Hα images of H II regions ionized by OB associations in the Large Magellanic Cloud (LMC) have revealed large (50–150 pc) gas shells around the OB associations and numerous small (<15 pc) ringlike nebulae outside the large shell (see, e.g., Davies, Elliott, & Meaburn 1976). These small nebulae are candidate windblown bubbles of single O or B stars (Weis & Duschl 1999) and offer perhaps the simplest test of the standard adiabatic bubble model.

We have investigated the kinematics and physical nature of three ringlike nebulae in N44 (Henize 1956) in the LMC. N44 is a bright H II complex with a 44 pc × 67 pc superbubble at the center and several compact H II regions along the shell rim. In the surrounding area, small dense H II regions, as well as extended diffuse nebulae, are also present at distances up to 160 pc. Figure 1 shows these features and their identifications given by Henize (1956). Three OB associations exist in N44 (Lucke & Hodge 1970); LH 47 in the central shell, LH 48 in the compact H II region N44 I, and LH 49 partially embedded in the bright H II region N44 D. The three nebulae that we have studied are N44 F, N44 J, and N44 M. N44 F is a bright circular H II region at the northwest rim of the superbubble and is adjacent to a bright
filament connected to the main nebula. In contrast, N44 J and N44 M, appearing, respectively, on the northern and eastern parts of N44, are fainter and relatively isolated. None of these three nebulae have been studied since their original identification by Henize (1956).

We have obtained ground-based CCD images and high-dispersion echelle spectra of N44 F, N44 J, and N44 M to study the morphology and kinematics of these nebulae. Additionally, we have used Hubble Space Telescope (HST) Wide Field Planetary Camera 2 (WFPC2) images of N44 F in the Hα and [S ii] lines to analyze its ionization structure. In this paper, we first describe these observations in § 2, then present the analysis and results for N44 F in § 3 and those for N44 J and N44 M in § 4. We present our conclusions in § 5.

2. OBSERVATIONS

The data sets used in this study include (1) CCD images taken with the Curtis Schmidt and 0.9 m telescopes at Cerro Tololo Inter-American Observatory (CTIO), (2) CCD images taken with the HST WFPC2, and (3) high-dispersion echelle spectra taken with the CTIO 4 m telescope. The high-dispersion spectra are useful to diagnose expanding shells that are not morphologically identifiable.

2.1. Ground-based CCD Images

CCD images of N44 were taken with the Curtis Schmidt telescope at CTIO in 1993 December. The detector was a front-illuminated Thomson 1024 × 1028 CCD camera with 19 µm pixels, or 1.835 pixel⁻¹. Images were obtained with Hα (λc = 6561 Å, Δλ = 26 Å), [O iii] (λc = 5010 Å, Δλ = 50 Å), and [S ii] (λc = 6720 Å, Δλ = 50 Å) filters for exposure times of 1800, 2700, and 2700 s, respectively. The Hα filter includes not only the Hα line but also the neighboring [N ii] λλ6548, 6583 lines. At the LMC’s radial velocity, 300 km s⁻¹, the [N ii] λ6548 line is redshifted further away from the red edge of the filter, but the [N ii] λ6584 line is redshifted further into the Hα bandpass. Using the [N ii]/ Hα intensity ratio measured from our echelle spectra (see § 2.3), we estimate that the [N ii] λ6548 line emission contributes 2.4%, 4.3%, and 3.3% of the total flux of N44 F, N44 J, and N44 M, respectively. This [N ii] contamination has been corrected in our Hα flux measurements.

![Fig. 1.—CTIO 0.9 m Hα (plus [N ii]) CCD image of N44, showing the nebular components defined by Henize (1956) and the OB associations cataloged by Lucke & Hodge (1970).](image)
Higher resolution Hα images were taken with the 0.9 m telescope at CTIO in 2000 December. The detector was a thinned AR-coated SITe 2048 × 2048 CCD with 24 μm pixels, or 0′′4 pixel⁻¹. The Hα filter (λc = 6559 Å, Δλ = 64 Å) used transmits Hα and both [N ii] lines; therefore the “Hα” images are really Hα plus [N ii] images and thus are used only for morphological analysis. The angular resolution, determined by the FWHM of the stellar images in the field of view, was approximately 1′′3. To map the entire N44 complex, five fields were observed with exposure times of 2 × 600 s for each field.

All CCD images were bias-subtracted and flat-fielded in a standard way using IRAF software, and multiple frames were combined to remove cosmic rays and improve the signal-to-noise ratio. Figure 1 shows the Hα mosaic of the N44 complex, and Fig. 2 presents close-ups of N44 F, N44 J, and N44 M in the Hα, [O iii], and [S ii] lines.

2.2. HST WFPC2 Images

HST WFPC2 images of N44 F were acquired via the Hubble Observation Problem Report7 (HOPR) observations of Cycle 6 program 6698. In these observations, made

---

7 The original observations of N44 were made with an incorrect orientation, resulting in a loss of 1/4 of the field of view. To compensate for the loss, HOPR observations were granted. To facilitate the scheduling of these HOPR observations and to maximize the scientific yield, a different pointing center in N44 suitable for arbitrary orientations was chosen.
with the F656N filter for 2 × 500 s and the F673N filter for 2 × 600 s, N44 F was included in the Wide-Field Camera 3. The F656N filter, centered at 6563.7 \AA{} with an FWHM of 21.4 \AA{}, includes the H\(\alpha\) line and the neighboring [N \textsc{ii}] lines. Using the [N \textsc{ii}]/H\(\alpha\) intensity ratio measured from our echelle spectra (see § 2.3), we estimate that the [N \textsc{ii}] \(\\lambda6548\) line emission contributes 2.4% of the flux in N44 F. This [N \textsc{ii}] contamination has been corrected in our H\(\alpha\) flux measurements. The F673N filter, centered at 6732.2 \AA{} with an FWHM of 47.2 \AA{} includes the nebular lines of [S \textsc{ii}] \(+[N \textsc{ii}]/H\alpha\).

The calibrated WFPC2 images were produced by the standard HST pipeline. We processed them further with IRAF and STSDAS routines. The images taken with the same filter were combined to remove cosmic rays and to produce a total exposure map. The combined [S \textsc{ii}] and H\(\alpha\) images were then each corrected for the intensity- and position-dependent charge transfer efficiency as explained by Holtzman et al. (1995). Following the recommended procedures for narrowband WFPC2 photometry, we find the rectangular widths of the F656N and F673N filters to be 28.3 and 63.3 \AA{}, respectively, and use these widths to convert the flux densities into fluxes.

Figure 3 shows the WFPC2 images of N44 F. To show the excitation variations, the [S \textsc{ii}]/H\(\alpha\) ratio map of N44 F is also presented, in addition to the H\(\alpha\) and [S \textsc{ii}] images.

2.3. CTIO 4 m Echelle Spectra

Echelle spectra were obtained with the CTIO 4 m telescope in 2000 December. The spectrograph was used with a 79 line mm\(^{-1}\) echelle grating and the long-focus red camera. We observed a single order centered on the H\(\alpha\) line by inserting a postslit H\(\alpha\) interference filter and replacing the cross-dispersing grating with a flat mirror. A Tektronix 2048 × 2048 CCD with 24 \(\mu\)m pixel\(^{-1}\) was used to record the images. This provided a spectral sampling of \(\\sim0.08\) \AA{} pixel\(^{-1}\) and a spatial sampling of 0′26 pixel\(^{-1}\). The wavelength coverage, limited by the H\(\alpha\) filter and the echelle order, was 125 \AA{}; the spatial coverage, limited by the optics, was \(\\sim200″\). The angular resolution, determined by the FWHM of the seeing, was approximately 1″. A slit width of 1′′65 was used. The resultant spectral resolution, measured from the ThAr lamp lines, was about 13 \(\text{km s}^{-1}\) FWHM.

Each of the three nebulae, N44 F, N44 J, and N44 M, was observed with an east-west oriented slit. The exposure times were 600 s for N44 F, but only 300 s for N44 J and N44 M. The spectral lines detected include nebular H\(\alpha\) and [N \textsc{ii}] lines and telluric H\(\alpha\) and OH lines (Osterbrock et al. 1996). We have adopted rest wavelengths of 6562.7885, 6548.080, and 6583.454 \AA{} for the H\(\alpha\) and [N \textsc{ii}] \(\\lambda6548, 6583\) nebular lines, respectively (Spyromilio 1995).

3. PHYSICAL STRUCTURE OF N44 F

We will first describe the overall morphology of N44 F, examine its excitation and ionization structure, and derive its rms electron density. Special emphasis is given to the prominent dust “pillars,” where star formation might be taking place. Next, we describe the kinematic features detected in the echelle spectra, fit Gaussian components to the line profiles, and use the resultant velocities to identify expanding structures and to determine expansion velocities. Finally, we combine the morphological and kinematic information and present an integrated view of this H \textsc{ii} region. Throughout this paper, we will adopt a distance of 50 kpc to the LMC (Feast 1999).

3.1. Morphology and Density

N44 F is a bright circular nebula nestled on a bright filament at the northwest rim of the superbubble in N44. In low-resolution H\(\alpha\) images, N44 F appears to have a doubling structure with a very bright region in the northwest.
The details of these features are resolved in the HST WFPC2 images. The outer ring, of radius ~22'', is surrounded by dusty features. Finger- or pillar-like dust columns, similar to those in the Eagle Nebula (=M16; Hester et al. 1996), are also seen at the periphery, with two especially prominent ones at the west, close to the brightest region of N44 F. These dust columns are revealed in detail by the HST images and will be discussed more extensively in § 3.2. The inner ring, of radius ~6'', is resolved into diffuse emission without sharp features. The western part of this ring merges into the brightest region of N44 F. A group of bright stars are located within the central ring, but they are substantially offset toward the bright emission region at the northwest. Unfortunately, none of the stars in the vicinity of N44 F have been studied photometrically or spectroscopically.

The [S ii] images of N44 F show a very different morphology: only the outer ring is visible and it is mostly composed of sharp filaments. The pillar-like features are also present and stars at the tips of two of them are clearly seen (see Fig. 4). The [S ii]/Hα ratio in the central region is very low, about 0.1. The outer ring possesses a higher [S ii]/Hα ratio, with values ranging from 0.2 to 0.4. Enhanced [S ii]/Hα ratios are often associated with shell structures or high-

![Fig. 4.—Close-up images of dust columns seen in N44 F through Hα, [S ii], and [S ii]/Hα (for exact position, see Fig. 3). Left, Dust columns situated at the west rim of N44 F (FOV = 18'' × 18''); right, dust columns situated at the south rim of N44 F (FOV = 14'' × 14''). The arrows point to the stars at the tips of the pillar-like dust columns.](image)
velocity shocks. As we do not find the latter in the nebula (see § 3.3), the somewhat elevated [S II]/H\alpha ratio is likely to result from the low-ionization parameter caused by the shell morphology. The values of [S II]/H\alpha are in fact similar to those seen in other shell structures (e.g., Lasker 1977; Hunter 1994).

Using the Curtis Schmidt images, we also examine the [O III] morphology of N44 F. Because of the poorer resolution, only the overall morphology can be described. The [O III] image of N44 F looks very similar to that in H\alpha, except for the bright H\alpha outer ring, which disappears almost completely in [O III]. We have used the HST WFPC2 observations of N44 C (Garnett, Galarza, & Chu 2000) to calibrate the observed [O III]/H\alpha ratio derived with the Curtis Schmidt images. The [O III]/H\alpha ratio of N44 F is relatively high, about 0.5–1.2 inside the ring, with the highest value near the stars. The outer ring has the lowest [O III]/H\alpha ratio, about 0.25. The integrated [O III]/H\alpha ratio for the whole nebula is about 0.55. The high ratio near the central region indicates that the ionizing source must be an early-type massive star.

The WFPC2 H\alpha image can be further analyzed to estimate the rms density of N44 F. A color excess of $E(B-V) = 0.11$ mag for N44 (Oey & Massey 1995) is adopted in the extinction correction. The emission measure $E$ estimate the rms density of N44 F. A color excess of $Q_f$ parameter.

### 3.2. Pillar-like Dust Columns

The dark clouds of N44 F exhibit new examples of the intriguing finger- or pillar-like structures, similar to those reported in the Eagle Nebula (Hester et al. 1996). The most prominent two are embedded in the bright northwest region (see Figs. 3 and 4). Several additional features of this type are present in the south and possibly in the southwest, but they are fainter. In Figure 4, we present the most striking of these structures in the H\alpha and [S II] images, as well as in the ratio map. The dust columns in N44 F are 5” to 10” long and 1” to 2” wide, corresponding to 1 to 2 pc long and 0.25 to 0.5 pc wide at the LMC’s distance. These sizes and morphologies are similar to those seen in 30 Doradus (Scowen et al. 1998) and M16 (Hester et al. 1996). Two of these columns harbor stars at their tips, as indicated by arrows in Figure 4. Hester et al. (1996) suggested that stars at the tips of pillars could be young stellar objects that were formed in the molecular cloud and finally merge after the photoevaporation of most of their parent cloud. However, the Hester et al. (1996) model of preexisting condensations in the molecular cloud does not provide the unique conditions for producing photoionized pillars. Hydrodynamical simulations by Williams, Ward-Thompson, & Whitworth (2001) illustrate that these structures can be formed by a variety of initial conditions in the structure with inhomogeneities in density and/or radiation field, but current observations do not yet permit discrimination among these different models. It is therefore of great interest to identify additional examples of such objects.

Other important characteristics of these dust columns are their ionization structure and their density. All the dust columns point toward the central ionizing source, i.e., a bright star or a small cluster between the center and the northwest edge of N44 F.

As can be seen in Figure 5, the [S II] peak is separated from the H\alpha peak by approximately 0.01, i.e., 0.02 pc, with H\alpha peaking slightly closer to the source of UV radiation that is photoevaporating the cloud. The shape of these profiles is very similar to those observed in the pillars of 30 Doradus or in ground-based images of M16 (Scowen et al.

---

9 The ionizing flux derived further can be used to estimate the ionization parameter $U \propto [Q(IP)]_{[2]}^{1/3}$, where $Q(IP)$ is the ionizing flux in photons per second, $n$ the density in cm$^{-3}$, and $f$ the filling factor. Using $Q(IP) = 1.0 \times 10^{49}$ photons s$^{-1}$, $n = 40$ cm$^{-3}$ and $f = 1 - [1 - (\Delta R/R)]^2 \sim 0.6$, we find a value of $\sim 10^{-3}$ for the ionization parameter.

10 We have compared N44 F, N44 J, and N44 M to the closest model available in Stasińska & Schaefer (1997), i.e., a spherical nebula of density $10^{-1}$ cm$^{-3}$ and metallicity 0.25 Z$_{\odot}$, ionized by one single star.
Unfortunately, no WFPC2 [O III] images of N44 F are available; thus we cannot undertake a complete analysis using photoionization models or constrain further the properties of the ionizing source. Following the method used in using photoionization models or constrain further the properties of the ionizing source. Following the method used in (see e.g., Weaver et al. 1977). With the observed radius \( R \) in parsecs and an expansion velocity of \( \dot{V} = 12 \text{ km s}^{-1} \), N44 F has a dynamical timescale of \( 2.7 \times 10^5 \text{ yr} \) and a \( L_{36}/n_0 \) ratio of 0.016 erg s\(^{-1}\) cm\(^{-3}\). If we assume that the shell consists of mass swept up from the volume, the ambient density, \( n_0 \), can be estimated by \( n_0 = 3n(\Delta R/R) \), where \( n \) is the rms density of the shell, \( \Delta R \) the shell thickness, and \( R \) the shell radius. For \( n \sim 40 \text{ cm}^{-3} \) and \( \Delta R/R = 0.25 \) (see § 3.1), we derive an ambient density of \( \sim 30 \text{ cm}^{-3} \) and a wind luminosity of \( \sim 5 \times 10^{35} \) ergs s\(^{-1}\). This wind luminosity is compatible with that expected from the spectral type determined in § 3.1, i.e., an O7 V star (de Jager, Nieuwenhuijzen, & van der Hucht 1988; Prinja, Barlow, & Howarth 1990). One uncertainty in these estimates is the shell thickness; however, even if the shell thickness is off by a factor of 2, the predicted wind luminosity will still be compatible, within the errors, with an O7 V star.

Thus, the dynamics of N44 F appear to be consistent with the standard adiabatic model for bubble evolution, within uncertainties generated by the complex interstellar environment. This contrasts with the results from superbubbles, which show evidence of retarded growth (e.g., Oey 1996). To investigate this discrepancy further, it is worth considering an alternative bubble model.

The presence of dust pillars around N44 F clearly indicates a highly inhomogeneous ISM. The photoevaporation of the dense clumps may serve as an energy sink and govern the dynamic evolution of this H II region. Since photoevaporation processes take place in the early evolutionary stages of a bubble or superbubble, the energy loss by photoevaporation may explain the smaller-than-expected sizes of previously studied superbubbles and Wolf-Rayet ring nebulae (see § 3.1). Therefore, we will now consider models of bubbles directly related to N44 F.

### 3.3. Kinematic Properties

The kinematic properties of N44 F are derived from the high-dispersion echelette observations of the H\(\alpha\) and [N II] \(\lambda 6583\) lines. The [N II] line has a smaller thermal width than the H\(\alpha\) line; thus it shows the line splitting better although it is noisier. We have extracted H\(\alpha\) and [N II] line profiles and fitted them with Gaussian components. The resultant velocity-position plot (Fig. 6) shows that N44 F is an expanding shell with a radius of \( 22^{\prime\prime} \), coincident with the outer ring described in § 3.1. Both lines indicate a shell expansion velocity of \( \sim 12 \text{ km s}^{-1} \). An example of the [N II] and H\(\alpha\) profiles are presented in Figure 7. The approaching (blue-shifted) component is fainter, suggesting a lower density.

Farther east, outside N44 F, an additional blue component is present, but it is probably associated with the complex filamentary structure at the outskirts of N44 and is not directly related to N44 F.

### 3.4. Test of the Standard Bubble Model

N44 F has a classical ring-nebula morphology, and its kinematics confirms an expanding shell, most likely created by the wind of the early-type massive star(s) within this bubble. We can now test whether the observed expansion dynamics of this bubble are consistent with those expected from the standard adiabatic bubble model (e.g., Weaver et al. 1977). With the observed radius \( R \) in parsecs and the expansion velocity \( V \) in kilometers per second, we can compute the dynamical timescale \( t_6 \) in units of \( 10^6 \text{ yr} \) by using

\[
t_6 = 0.6 R/V
\]

and further determine the ratio of stellar wind luminosity \( L_{36} \) in units of \( 10^{36} \text{ ergs s}^{-1} \) to ambient density \( n_0 \) in units of \( \text{H atoms cm}^{-3} \), using

\[
R = 27 \left( \frac{L_{36}}{n_0} \right)^{1/5} t_6^{-3/5}.
\]

For a radius of \( 5.3 \text{ pc} \) and an expansion velocity of \( \sim 12 \text{ km s}^{-1} \), N44 F has a dynamical timescale of \( 2.7 \times 10^5 \text{ yr} \) and a \( L_{36}/n_0 \) ratio of 0.016 erg s\(^{-1}\) cm\(^{-3}\). If we assume that the shell consists of mass swept up from the volume, the ambient density, \( n_0 \), can be estimated by \( n_0 = 3n(\Delta R/R) \), where \( n \) is the rms density of the shell, \( \Delta R \) the shell thickness, and \( R \) the shell radius. For \( n \sim 40 \text{ cm}^{-3} \) and \( \Delta R/R = 0.25 \) (see § 3.1), we derive an ambient density of \( \sim 30 \text{ cm}^{-3} \) and a wind luminosity of \( \sim 5 \times 10^{35} \text{ ergs s}^{-1} \). This wind luminosity is compatible with that expected from the spectral type determined in § 3.1, i.e., an O7 V star (de Jager, Nieuwenhuijzen, & van der Hucht 1988; Prinja, Barlow, & Howarth 1990). One uncertainty in these estimates is the shell thickness; however, even if the shell thickness is off by a factor of 2, the predicted wind luminosity will still be compatible, within the errors, with an O7 V star.

Thus, the dynamics of N44 F appear to be consistent with the standard adiabatic model for bubble evolution, within uncertainties generated by the complex interstellar environment. This contrasts with the results from superbubbles, which show evidence of retarded growth (e.g., Oey 1996). To investigate this discrepancy further, it is worth considering an alternative bubble model.

The presence of dust pillars around N44 F clearly indicates a highly inhomogeneous ISM. The photoevaporation of the dense clumps may serve as an energy sink and govern the dynamic evolution of this H II region. Since photoevaporation processes take place in the early evolutionary stages of a bubble or superbubble, the energy loss by photoevaporation may explain the smaller-than-expected sizes of previously studied superbubbles and Wolf-Rayet ring nebulae (see § 3.1). Therefore, we will now consider models of bubbles
formed in a cloudy medium by McKee, Van Buren, & Lazareff (1984). In their models, only bubbles blown by stars with weak winds will follow the Weaver et al. model, while stars with stronger winds will produce bubbles whose expansion is governed by the dynamics of photoevaporating clouds. They define a dimensionless wind luminosity

\[ L_w^* = \frac{L_w}{[1.26 \times 10^{36} (S_{49}/n_m)^{1/3}]} \]

and a homogenization radius

\[ R_h(\text{pc}) = 0.009 t^{4/7} \left( \frac{S_{49}}{n_m^2} \right)^{1/7}, \]

where \( L_w \) is the wind luminosity in ergs s\(^{-1}\), \( S_{49} \) the ionizing flux in photons s\(^{-1}\), \( n_m \) the mean cloud density in cm\(^{-3}\) and \( t \) the dynamical timescale in years. Strong winds possess \( L_w^* \approx 1 \) and blow bubbles of radius \( R_h \).
Using the observed parameters of N44 F (with $n_w = n_0$) and assuming a stellar wind luminosity for an O7 V star, we estimate $L_C/\rho_{\rm C3} \approx 1$ and $R_b \approx 4.5$ pc, close to the observed bubble’s radius. This seems to suggest that the dynamics of photoevaporation actually governs the bubble’s expansion. The agreement of the data with both models could be a simple coincidence, or maybe the bubble has just encountered the cloudy medium and begun the photoevaporation processes, in which case there may not be a large deviation from the Weaver et al. model. Note, however, that all these conclusions hinge upon the validity of the stellar wind luminosity, which is based on an assumed spectral type of the central star. Future study of the actual stellar content of N44 F is needed to place stronger constraints on the applicable bubble models.

4. PHYSICAL STRUCTURE OF N44 J AND N44 M

4.1. N44 J

Situated in the northernmost part of the N44 complex, N44 J is a slightly elongated, ringlike nebula of size $37'' \times 32''$ (or $9.0$ pc $\times$ $7.8$ pc). The $0.9$ m H$\alpha$ image shows a bright rim around dusty features at the northwest boundary. A bright central star is visible in the H$\alpha$ and [S ii] images (see Fig. 2). In H$\alpha$ and [S ii], the nebula exhibits modest limb-brightening, with the edge-to-center brightness ratio less than 2, while its central part displays a rather uniform surface brightness. The [S ii]/H$\alpha$ ratio is very similar to that of N44 F, ranging from 0.25 to 0.4. In contrast, the [O iii] image of N44 J shows emission only near the central star. The [O iii]/H$\alpha$ ratio is 0.4 near the star, and only 0.05–0.08 elsewhere, significantly lower than the corresponding value in N44 F. The integrated [O iii]/H$\alpha$ ratio of N44 J is about 0.12.

The observed H$\alpha$ flux of N44 J is $5.7 \times 10^{-12}$ ergs cm$^{-2}$ s$^{-1}$. This requires an ionizing flux $Q(H^0)$ of $1.6 \times 10^{48}$ photons s$^{-1}$ when adopting $E(B-V) = 0.11$ mag, or $2.3 \times 10^{48}$ photons s$^{-1}$ for $E(B-V) = 0.28$ mag. These values are expected for an O9.5 V–B0 V type ionizing star (Panagia 1973; Vacca et al. 1996; Schaerer & de Koter 1997), which is fully consistent with that suggested by the [O iii]/H$\alpha$ ratio of the nebula (Stasińska & Schaerer 1997). Assuming a spherical geometry, we derive an rms electron density of $25$ cm$^{-3}$, slightly less dense than N44 F. The ionized gas mass of N44 J is then $200 M_{\odot}$.

The echelle spectrum of N44 J shows a kinematically quiescent H ii region. The centroids of the H$\alpha$ and [N ii] lines are centered at 292 km s$^{-1}$, with an rms variation of 3 km s$^{-1}$ (see Figs. 6 and 7). No line splitting is seen. The observed FWHMs are $27 \pm 1$ km s$^{-1}$ for H$\alpha$ and $16 \pm 2$ km s$^{-1}$ for [N ii]. These observed line widths imply a turbulent FWHM of about 10 km s$^{-1}$ for H$\alpha$ and 8 km s$^{-1}$ for [N ii] if we take into account the instrumental profile and the thermal broadening at 10$^4$ K. The turbulence can thus explain the small variations of the centroid velocity. The difference between the turbulence widths is probably caused by a difference in the emission regions of the two lines. If N44 J is actually expanding, the expansion velocity should be very small, less than 8 km s$^{-1}$. For such small expansion velocity, no strong compression is expected, hence no sharp filaments should be seen.

Finally, we may compare the observations with the standard adiabatic bubble model. As the density in the ringlike nebula is a few tens cm$^{-3}$, we will assume in our calculations a density of 10 cm$^{-3}$ in the ISM. For an expected wind luminosity of $\sim 3 \times 10^{34}$ ergs s$^{-1}$ for an O9.5 V star (de Jager et al. 1988; Prinja et al. 1990) and with the observed 17''5 radius of N44 J, the Weaver et al. (1977) model predicts an expansion velocity of about 8 km s$^{-1}$ for N44 J. This...
expected expansion velocity is just at the limit implied by the velocity widths of the H$\alpha$ and [N ii] lines. Raising the ambient density by a factor of 2 can lower the expected expansion velocity to 6.5 km s$^{-1}$, which is more consistent with the observed limit. We conclude that the observed bubble dynamics of N44 J does not greatly contradict the model predictions.

4.2. N44 M

On the southeast part of N44, another small ringlike nebula is present: N44 M. It is the faintest nebula of our sample. It shows a ring with a radius of $\sim 22''$ (or 5.3 pc), but its north boundary is not well defined (see Fig. 2). The sharp southwest boundary suggests the presence of dust clouds. Several bright stars appear in its interior. N44 M possesses an excitation structure very similar to N44 J. The [S ii]/H$\alpha$ ratio of N44 M is comparable to that in N44 F, but the [O iii]/H$\alpha$ ratio of N44 M is much lower, ranging from 0.07 to 0.16 in the nebula and rising to 0.4 near the stars. The integrated [O iii]/H$\alpha$ ratio of N44 M is about 0.18.

With an observed H$\alpha$ flux of $5.3 \times 10^{-12}$ ergs cm$^{-2}$ s$^{-1}$ and the two evaluations of the extinction, the required ionizing flux ($Q$(H$\alpha$)) is $(1.5-2.1) \times 10^{48}$ photons s$^{-1}$. This suggests an O9–B0 V type ionizing star (Panagia 1973; Vacca et al. 1996; Schaerer & de Koter 1997), which is again compatible with the [O iii]/H$\alpha$ ratio (Stasinska & Schaerer 1997). If we assume a spherical geometry, we find that the rms density is about $17$ cm$^{-3}$ and the estimated mass of the nebula $\sim 275 M_{\odot}$.

The echelle spectrum of N44 M shows only one component, centered at 298 km s$^{-1}$ with a rms variation of 1 km s$^{-1}$ and an FWHM of 28 $\pm$ 1 km s$^{-1}$ in the H$\alpha$ line and 20 $\pm$ 4 km s$^{-1}$ in the [N ii] line (see Figs. 6 and 7). The turbulent FWHMs are then 12 km s$^{-1}$ for H$\alpha$ and 14 km s$^{-1}$ for [N ii]. With an observed radius of $\sim 22''$, a density of 10 cm$^{-3}$ for the ISM, and a O9.5 V ionizing star (see § 4.1), the standard bubble model predicts an expansion velocity of $\sim 7$ km s$^{-1}$ for N44 M, which appears consistent with the upper limit of the echelle observations.

The kinematic characteristics of N44 J and N44 M are very similar, despite the somewhat different morphology. Neither H ii region contains shells expanding at velocities greater than $\sim 8$ km s$^{-1}$. In the future, additional observations may enable a better comparison of these nebulae with the standard model. Precise photometry and/or stellar spectroscopy would give accurate information about the stellar content of these nebulae, while nebular spectra with higher resolution should more strongly constrain the kinematics of N44 J and N44 M. Thus, improved data are needed to more stringently test the standard model for N44 J and N44 M. We also report the discovery of several dust pillars in N44 F, which are similar to those found in the Eagle Nebula (Hester et al. 1996) and 30 Doradus (Scowen et al. 1998). These structures are indicative of the evaporation of molecular clouds by the ionizing source. The examples in N44 F are especially well-suited to investigating the process and role of photoevaporation in star formation and shell evolution, because of their location within such a well-defined, windblown bubble. We found that photoevaporation, as evidenced by the pillar structure, may be dynamically important for the shell evolution in N44 F, slowing down the expanding shell and inhibiting its growth. These photoevaporation processes may thus undermine the seeming agreement between the observed bubble dynamics and the simple adiabatic bubble model.

We thank Charles Danforth for assisting in the echelle observations and Rosie Chen for help in the HST WFPC2 image reduction. This work has been supported by the NASA grant STScI-GO-6698.01-95A. Y. N. acknowledges support from the F.N.R.S., contracts P4/05 and P5/36 “Pôle d’Attraction Interuniversitaire” (SSTC-Belgium) and the PRODEX XMM-OM and Integral Projects. R. C. S. acknowledges the support of the Dean B. McLaughlin fellowship at the University of Michigan and NSF grant AST 95-30747.
