Abstract

Recovery of the initial state of a high-dimensional system can require a large number of measurements. In this paper, we explain how this burden can be significantly reduced when randomized measurement operators are employed. Our work builds upon recent results from Compressive Sensing (CS). In particular, we make the connection to CS analysis for random block diagonal matrices. By deriving Concentration of Measure (CoM) inequalities, we show that the observability matrix satisfies the Restricted Isometry Property (RIP) (a sufficient condition for stable recovery of sparse vectors) under certain conditions on the state transition matrix. For example, we show that if the state transition matrix is unitary, and if independent, randomly-populated measurement matrices are employed, then it is possible to uniquely recover a sparse high-dimensional initial state when the total number of measurements scales linearly in the sparsity level (the number of non-zero entries) of the initial state and logarithmically in the state dimension. We further extend our RIP analysis for scaled unitary and symmetric state transition matrices. We support our analysis with a case study of a two-dimensional diffusion process.

I. INTRODUCTION

In this paper, we consider the problem of recovering the initial state of a high-dimensional system from compressive measurements (i.e., we take fewer measurements than the system dimension).

A. Measurement Burdens in Observability Theory

Consider an $N$-dimensional discrete-time linear dynamical system described by the state equation

\begin{align}
    x_k &= Ax_{k-1} \\
    y_k &= C_k x_k,
\end{align}

(1)

where $x_k \in \mathbb{R}^N$ represents the state vector at time $k \in \{0, 1, 2, \ldots \}$, $A \in \mathbb{R}^{N \times N}$ represents the state transition matrix, $y_k \in \mathbb{R}^M$ represents a set of measurements (or “observations”) of the state at time $k$, and $C_k \in \mathbb{R}^{M \times N}$ represents the measurement matrix at time $k$. (Observe that the number of measurements at each sample time is $M$.) For any finite set $\Omega \subset \{0, 1, 2, 3, \ldots \}$, define the generalized observability matrix as

\begin{equation}
    O_\Omega := \begin{bmatrix}
        C_{k_0} A^{k_0} \\
        C_{k_1} A^{k_1} \\
        \vdots \\
        C_{k_{K-1}} A^{k_{K-1}}
    \end{bmatrix} \in \mathbb{R}^{MK \times N},
\end{equation}

(2)

where $\Omega = \{k_0, k_1, \ldots, k_{K-1}\}$ contains $K$ observation times. Note that this definition extends the traditional definition of the observability matrix by allowing arbitrary time samples in (2) and matches the traditional definition when $\Omega = \{0, 1, 2, \ldots, K-1\}$. The primary use of observability theory is in ensuring that a state (say, an initial state $x_0$) can be recovered from a collection of measurements $\{y_{k_0}, y_{k_1}, \ldots, y_{k_{K-1}}\}$. In particular, defining $y_\Omega := \begin{bmatrix} y_{k_0}^T & y_{k_1}^T & \cdots & y_{k_{K-1}}^T \end{bmatrix}^T \in \mathbb{R}^{MK}$, we have

\begin{equation}
    y_\Omega = O_\Omega x_0.
\end{equation}

(3)

Although we will consider situations where $C_k$ changes with each $k$, we first discuss the classical case where $C_k = C$ ($C$ is assumed to have full row rank) for all $k$ and $\Omega = \{0, 1, \ldots, K-1\}$ (the observation times are consecutive). In this setting, an important and classical result [2] states that a system described by the state equation (1) is observable if and only if $O_\Omega$ has rank $N$ (full column rank) where $\Omega = \{0, 1, \ldots, N-1\}$. One challenge in exploiting this fact is that for some systems, $N$ can be quite large. For example, distributed systems evolving on a spatial domain can have a large state space

\footnote{The results of this paper also apply directly to systems described by a state equation of the form

\begin{align}
    x_k &= Ax_{k-1} + Bu_k \\
    y_k &= C_k x_k + Du_k,
\end{align}

where $u_k \in \mathbb{R}^P$ is the input vector at sample time $k$ and $B \in \mathbb{R}^{N \times P}$ and $D \in \mathbb{R}^{M \times P}$ are constant matrices. Indeed, initial state recovery is independent of $B$ and $D$ when it is assumed that the input vector $u_k$ is known for all sample times $k$.}
even after taking a spatially-discretized approximation. In such settings, we might therefore require a very large total number of measurements \( MK \) with \( K = N \) to identify an initial state, and moreover, inverting the matrix \( O_{12} \) could be very computationally demanding.

This raises an interesting question: under what circumstances might we be able to infer the initial state of a system when \( MK < N \)? We might imagine, for example, that the measurement burden could be alleviated in cases when there is a model for the state \( x_0 \) that we wish to recover. Alternatively, we may have cases where, rather than needing to recover \( x_0 \) from \( y_{\Omega} \), we desire only to solve a much simpler inference problem such as a binary detection or a classification problem. In this paper, inspired by the emerging theory of Compressive Sensing (CS) \([3]–[5]\), we explain how such assumptions can indeed reduce the measurement burden and, in some cases, even allow recovery of the initial state when \( MK < N \) and the system of equations (3) is guaranteed to be underdetermined. More broadly, exploiting CS concepts in the analysis of sparse dynamical systems from limited information has gained much attention over the last few years in applications such as system identification \([6]–[9]\), control feedback design \([10]\), and interconnected networks \([11], [12]\).

B. Compressive Sensing and Randomized Measurements

The CS theory states that it is possible to solve certain rank-deficient sets of linear equations by imposing a model assumption on the signal to be recovered. In particular, suppose \( y = \Phi x \) where \( \Phi \) is an \( \tilde{M} \times N \) matrix with \( \tilde{M} < N \). Suppose also that \( x \in \mathbb{R}^N \) is \( S \)-sparse, meaning that only \( S \) out of its \( N \) entries are non-zero.\(^2\) If \( \Phi \) satisfies a condition called the Restricted Isometry Property (RIP) of order \( 2S \) for a sufficiently small isometry constant \( \delta_{2S} \), then it is possible to uniquely recover any \( S \)-sparse signal \( x \) from the measurements \( y = \Phi x \) using a tractable convex optimization program known as \( \ell_1 \)-minimization \([3], [4]\). The RIP also ensures that the recovery process is robust to noise and stable in cases where \( x \) is not precisely sparse \([13]\). In the following, we provide the definition of the RIP.

**Definition 1:** A matrix \( \Phi \in \mathbb{R}^{\tilde{M} \times N} (\tilde{M} < N) \) is said to satisfy the RIP of order \( S \) with isometry constant \( \delta_S \in (0, 1) \) if

\[
(1 - \delta_S)\|x\|_2^2 \leq \|\Phi x\|_2^2 \leq (1 + \delta_S)\|x\|_2^2
\]

holds for all \( S \)-sparse vectors \( x \in \mathbb{R}^N \).

Observe that the RIP is a property of a matrix and has a deterministic definition. However, checking whether the RIP is a property of a matrix and has a deterministic definition. However, checking whether the RIP holds for a given matrix \( \Phi \) is computationally expensive and is almost impossible when

\(^2\)This is easily extended to the case where \( x \) is sparse in some transform domain.
$N$ is large. A common way to establish the RIP for $\Phi$ is to populate $\Phi$ with random entries. If $\Phi$ is populated with independent and identically distributed (i.i.d.) Gaussian random variables having zero mean and variance $\frac{1}{M}$, for example, then $\Phi$ will satisfy the RIP of order $S$ with isometry constant $\delta_S$ with very high probability when $\widetilde{M}$ is proportional to $\delta_S^{-2} S \log \frac{N}{S}$ [5], [14], [15]. This result is significant because it indicates that the number of measurements sufficient for correct recovery scales linearly in the sparsity level $S$ and only logarithmically in the ambient dimension $N$. Other random distributions may also be considered, including matrices with uniform entries of random signs. Consequently, a number of new sensing hardware architectures, from analog-to-digital converters to digital cameras, are being developed to take advantage of the benefits of random measurements [16]–[19].

A simple way [14], [20] of proving the RIP for a randomized construction of $\Phi$ involves first showing that the matrix satisfies a Concentration of Measure (CoM) inequality akin to the following.

**Definition 2:** A random matrix (a matrix whose entries are drawn from a particular probability distribution) $\Phi \in \mathbb{R}^{\widetilde{M} \times N}$ is said to satisfy the Concentration of Measure (CoM) inequality if for any fixed signal $x \in \mathbb{R}^N$ (not necessarily sparse) and any $\epsilon \in (0, 1)$,

$$P \left\{ \left| \| \Phi x \|_2^2 - \| x \|_2^2 \right| > \epsilon \| x \|_2^2 \right\} \leq 2 \exp \left\{ -\widetilde{M} f(\epsilon) \right\},$$

where $f(\epsilon)$ is a positive constant that depends on the isometry constant $\epsilon$, and $\tau \leq 1$ is some maximum value of the isometry constant for which the CoM inequality holds.

Note that the failure probability in (5) decays exponentially fast in the number of measurements $\widetilde{M}$ times some constant $f(\epsilon)$ that depends on the isometry constant $\epsilon$. For most interesting random matrices, including matrices populated with i.i.d. Gaussian random variables, $f(\epsilon)$ is quadratic in $\epsilon$ as $\epsilon \rightarrow 0$.

Baraniuk et al. [14] and Mendelson et al. [21] showed that a CoM inequality of the form (5) can be used to prove the RIP for random compressive matrices. This result is rephrased by Davenport [15].

**Lemma 1:** [15] Let $\mathcal{X}$ denote an $S$-dimensional subspace in $\mathbb{R}^N$. Let $\delta_S \in (0, 1)$ denote a distortion factor and $\nu \in (0, 1)$ denote a failure probability, and suppose $\Phi$ is an $\widetilde{M} \times N$ random matrix that satisfies the CoM inequality (5) with $\widetilde{M} \geq \frac{S \log (\frac{2\log (\frac{2N}{S})}{\nu})}{f(\frac{\delta_S}{2})}$.

Then with probability at least $1 - \nu$, for all $x \in \mathcal{X}$,

$$(1 - \delta_S) \| x \|_2^2 \leq \| \Phi x \|_2^2 \leq (1 + \delta_S) \| x \|_2^2.$$

Through a union bound argument (see, for example, Theorem 5.2 in [14]) and by applying Lemma 1 for all $S$-dimensional subspaces that define the space of $S$-sparse signals in $\mathbb{R}^N$, one can show that $\Phi$ satisfies the RIP (of order $S$ and with isometry constant $\delta_S$) with high probability when $\widetilde{M}$ scales linearly in $S$ and logarithmically in $N$.
C. Observability from Random, Compressive Measurements

In order to exploit CS concepts in observability analysis, we consider scenarios where the measurement matrices $C_k$ are populated with random entries. Physically, such randomized measurements may be taken using the types of CS protocols and hardware mentioned above. Our analysis is therefore appropriate in cases where one has some control over the sensing process.

As is apparent from (2), even with randomness in matrices $C_k$, the observability matrix $O_\Omega$ contains some structure and cannot be simply modeled as a matrix populated with i.i.d. Gaussian random variables and thus, existing results cannot be directly applied. Our work builds on a recent paper by Park et al. in which CoM inequalities are derived for random block diagonal matrices [22]. Our concentration results cover a large class of systems (not necessarily unitary) and initial states (not necessarily sparse), and apart from guaranteeing recovery of sparse initial states, other inference problems concerning $x_0$, such as detection or classification of more general initial states and systems, can also be solved using random, compressive measurements, and the performance of such techniques can be studied using the CoM bounds that we provide [23].

Our CoM results have important implications for establishing the RIP. Such RIP results provide a sufficient number of measurements for exact initial state recovery when the initial state is known to be sparse a priori. The results of this paper show that under certain conditions on $A$ (e.g., for unitary, scaled unitary, and certain symmetric matrices $A$), the observability matrix $O_\Omega$ will satisfy the RIP with high probability when the total number of measurements $MK$ scales linearly in $S$ and logarithmically in $N$.

Before going into the details of the derivations and proofs, we first state in Section II our main results on establishing the RIP for the observability matrix. We then present in Section III the CoM results upon which the conclusions for establishing the RIP are based. Finally, in Section IV we support our results with a case study involving a diffusion process starting from a sparse initial state.

D. Related Work

Questions involving observability in compressive measurement settings have also been raised in a recent paper [24] concerned with tracking the state of a system from nonlinear observations. Due to the intrinsic nature of the problems in that paper, however, the observability issues raised are quite different. For example, one argument appears to assume that $M \geq S$, a requirement that we do not have. In a recent technical report [25], Dai et al. have also considered a similar sparse initial state recovery problem. However, their approach is different and the results are only applicable in noiseless and perfectly sparse initial state recovery problems. In this paper, we establish the RIP for the observability matrix, which
implies not only that perfectly sparse initial states can be recovered exactly when the measurements are noiseless but also that the recovery process is robust with respect to noise and that nearly-sparse initial states can be recovered with high accuracy \cite{13}. Finally, we note that a matrix vaguely similar to the observability matrix has been studied by Yap et al. in the context of quantifying the memory capacity of echo state networks \cite{26}. The recovery results and guarantees presented in this paper are substantially different from the above mentioned papers as we derive CoM inequalities for the observability matrix and then establish the RIP based on these CoM inequalities.

II. Restricted Isometry Property and the Observability Matrix

When the observability matrix $O_\Omega$ satisfies the RIP of order $2S$ with isometry constant $\delta_{2S} < \sqrt{2} - 1$, an initial state with $S$ or fewer non-zero elements can be stably recovered by solving an $\ell_1$-minimization problem \cite{13}. (Similar statements can be made for recovery using various iterative greedy algorithms \cite{27}–\cite{30}.) In this section, we present cases where the total number of measurements sufficient for establishing the RIP scales linearly in $S$ and only logarithmically in the state dimension $N$. As in standard observability theory, the state transition matrix $A$ plays a crucial role in the analysis. Because the analysis is somewhat complex, results for completely general $A$ are difficult to obtain. However, we present results here for unitary, scaled unitary, and certain symmetric matrices, and we believe that these can give interesting insight into the essential issues driving the initial state recovery problem.

To assist in interpreting the RIP results, let us point out that we actually state our RIP bounds in terms of the scaled observability matrix $\frac{1}{\sqrt{b}}O_\Omega$ where $b$ is defined below and is chosen to ensure that the measurements are properly normalized to be compatible with (4). In noiseless recovery, this scaling is unimportant. When noise occurs, however, the scaling enters into the effective signal to noise ratio for the problem, as the measurements will be more sensitive to noise when $b$ is small.

Our first result, stated in Theorem 1, applies to a system with dynamics represented by a scaled unitary matrix when measurements are taken at the first $K$ sample times, starting at zero.

\textbf{Theorem 1:} Assume $\Omega = \{0, 1, \ldots, K - 1\}$. Suppose that $A \in \mathbb{R}^{N \times N}$ can be represented as $A = aU$ where $a \in \mathbb{R} \ (a \neq 0)$ and $U \in \mathbb{R}^{N \times N}$ is unitary. Define $b := 1 + a^2 + a^4 + \cdots + a^{2(K-1)}$. Assume each of the measurement matrices $C_k \in \mathbb{R}^{M \times N}$ is populated with i.i.d. Gaussian random entries with mean zero and variance $\frac{1}{M}$. Assume all matrices $C_k$ are generated independently of each other. Suppose that $N$, $S$, and $\delta_S \in (0, 1)$ are given. Then with probability exceeding $1 - \nu$, $\frac{1}{\sqrt{b}}O_\Omega$ satisfies the RIP of order...
S with isometry constant $\delta_S$ whenever

$$MK \geq \begin{cases} \frac{512 \left( (1 - a^2)K + a^2 \right) \left( S \left( \log \left( \frac{22}{\delta_S} \right) + 1 + \log \left( \frac{N}{S} \right) \right) + \log \left( \frac{2}{\nu} \right) \right)}{\delta_S}, & |a| < 1 \\ \frac{512 \left( (1 - a^{-2})K + a^{-2} \right) \left( S \left( \log \left( \frac{22}{\delta_S} \right) + 1 + \log \left( \frac{N}{S} \right) \right) + \log \left( \frac{2}{\nu} \right) \right)}{\delta_S}, & |a| > 1 \end{cases}$$

(6) (7)

**Proof** See Section III-A2.

One should note that when $A = aU$ ($a \neq 1$), the results of Theorem 1 have a dependency on $K$ (the number of sampling times). This dependency is not desired in general. When $a = 1$ (i.e., $A$ is unitary), a result (Theorem 2) can be obtained in which the total number of measurements $MK$ scales linearly in $S$ and with no dependency on $K$. Our general results for $A = aU$ also indicate that when $|a|$ is close to the origin (i.e., $|a| \ll 1$), and by symmetry when $|a| \gg 1$, worse recovery performance is expected as compared to the case when $a = 1$. When $|a| \ll 1$, as an example, the effect of the initial state will be highly attenuated as we take measurements at later times. A similar intuition holds when $|a| \gg 1$. When $a = 1$ (i.e., unitary $A$), we can relax the consecutive sample times assumption in Theorem 1 (i.e., $\Omega = \{0, 1, \ldots, K - 1\}$). We have the following RIP result when $K$ arbitrarily-chosen samples are taken.

**Theorem 2:** Assume $\Omega = \{k_0, k_1, \ldots, k_{K-1}\}$. Suppose that $A \in \mathbb{R}^{N \times N}$ is unitary. Assume each of the measurement matrices $C_k \in \mathbb{R}^{M \times N}$ is populated with i.i.d. Gaussian random entries with mean zero and variance $\frac{1}{M}$. Assume all matrices $C_k$ are generated independently of each other. Suppose that $N, S$, and $\delta_S \in (0, 1)$ are given. Then with probability exceeding $1 - \nu$, $\frac{1}{\sqrt{K}} O_\Omega$ satisfies the RIP of order $S$ with isometry constant $\delta_S$ whenever

$$MK \geq \frac{512 \left( S \left( \log \left( \frac{22}{\delta_S} \right) + 1 + \log \left( \frac{N}{S} \right) \right) + \log \left( \frac{2}{\nu} \right) \right)}{\delta_S}.$$

(8)

**Proof** See Section III-A2.

Theorem 2 states that under the assumed conditions, $\frac{1}{\sqrt{K}} O_\Omega$ satisfies the RIP of order $S$ with isometry constant $\delta_S$ with high probability when the total number of measurements $MK$ scales linearly in the sparsity level $S$ and logarithmically in the state ambient dimension $N$. Consequently under these assumptions, *unique* recovery of any $S$-sparse initial state $x_0$ is possible from $y_\Omega = O_\Omega x_0$ by solving the $\ell_1$-minimization problem or using various iterative greedy algorithms [27], [29] whenever $MK$ is proportional to $S \log \left( \frac{N}{S} \right)$. This is in fact a significant reduction in the sufficient total number of measurements for correct initial state recovery as compared to traditional observability theory.
We further extend our analysis and establish the RIP for certain symmetric matrices $A$. We believe this analysis has important consequences in analyzing problems of practical interest such as diffusion (see, for example, Section IV). Suppose $A \in \mathbb{R}^{N \times N}$ is a positive semidefinite matrix with the eigendecomposition

$$A = U \Lambda U^T = [U_1 | U_2] \begin{bmatrix} \Lambda_1 & 0 \\ 0 & \Lambda_2 \end{bmatrix} [U_1 | U_2]^T,$$

where $U \in \mathbb{R}^{N \times N}$ is unitary, $\Lambda \in \mathbb{R}^{N \times N}$ is a diagonal matrix with non-negative entries, $U_1 \in \mathbb{R}^{N \times L}$, $U_2 \in \mathbb{R}^{N \times (N-L)}$, $\Lambda_1 \in \mathbb{R}^{L \times L}$, and $\Lambda_2 \in \mathbb{R}^{(N-L) \times (N-L)}$. The submatrix $\Lambda_1$ contains the $L$ largest eigenvalues of $A$. The value for $L$ can be chosen as desired; our results below give the strongest bounds when all eigenvalues in $\Lambda_1$ are large compared to all eigenvalues in $\Lambda_2$. Let $\lambda_{1,\min}$ denote the smallest entry of $\Lambda_1$, $\lambda_{1,\max}$ denote the largest entry of $\Lambda_1$, and $\lambda_{2,\max}$ denote the largest entry of $\Lambda_2$.

In the following, we show that in the special case where the matrix $U_1^T \in \mathbb{R}^{L \times N}$ ($L < N$) happens to itself satisfy the RIP (up to a scaling), then $O_\Omega$ satisfies the RIP (up to a scaling). Although there are many state transition matrices $A$ that do not have a collection of eigenvectors $U_1$ with this special property, we do note that if $A$ is a circulant matrix, its eigenvectors will be the Discrete Fourier Transform (DFT) basis vectors, and it is known that a randomly selected set of DFT basis vectors will satisfy the RIP with high probability [31].

**Theorem 3:** Assume $\Omega = \{k_0, k_1, \ldots, k_{K-1}\}$. Assume $A$ has the eigendecomposition given in (9) and $U_1^T \in \mathbb{R}^{L \times N}$ ($L < N$) satisfies a scaled version of the RIP of order $S$ with isometry constant $\delta_S$. Formally, assume for $\delta_S \in (0, 1)$ that

$$(1 - \delta_S) \frac{L}{N} \|x_0\|_2 \leq \|U_1^T x_0\|_2 \leq (1 + \delta_S) \frac{L}{N} \|x_0\|_2$$

holds for all $S$-sparse $x_0 \in \mathbb{R}^N$. Assume each of the measurement matrices $C_k \in \mathbb{R}^{M \times N}$ is populated with i.i.d. Gaussian random entries with mean zero and variance $\frac{1}{M}$. Assume all matrices $C_k$ are generated independently of each other. Let $\nu \in (0, 1)$ denote a failure probability and $\delta \in (0, \frac{16}{\sqrt{M}})$ denote a distortion factor. Then with probability exceeding $1 - \nu$,

$$(1 - \delta) \left(1 - \delta_S \right) \frac{L}{N} \sum_{i=0}^{K-1} \lambda_{1,\min}^{2k_i} \leq \|O_\Omega x_0\|_2 \leq (1 + \delta) \left(1 + \delta_S \right) \frac{L}{N} \sum_{i=0}^{K-1} \lambda_{1,\max}^{2k_i} + \sum_{i=0}^{K-1} \lambda_{2,\max}^{2k_i}$$

for all $S$-sparse $x_0 \in \mathbb{R}^N$ whenever

$$MK \geq \frac{512K}{\rho \delta^2} \left(S \left(\log(\frac{N}{K}) + 1 + \log(\frac{N}{2})\right) + \log(\frac{2}{\nu})\right).$$

The $\frac{1}{N}$ scaling in (10) is to account for the unit-norm rows of $U_1^T$. 

May 5, 2014

DRAFT
Then with probability exceeding $1 - \nu$, 

$$\rho := \inf_{S\text{-sparse } x_0 \in \mathbb{R}^N} \Gamma(A_0 x_0)$$

and

$$\Gamma(A_0 x_0) := \frac{\|A^{k_0} x_0\|_2 + \|A^{k_1} x_0\|_2 + \cdots + \|A^{k_{K-1}} x_0\|_2}{\|A^{k_0} x_0\|_2^2 + \|A^{k_1} x_0\|_2^2 + \cdots + \|A^{k_{K-1}} x_0\|_2^2}. $$

**Proof** See Appendix A.

The result of Theorem 3 is particularly interesting in applications where the largest eigenvalues of $A$ all cluster around each other and the rest of the eigenvalues cluster around zero. Put formally, we are interested in applications where

$$0 \approx \lambda_{2,\max} \ll \frac{\lambda_{1,\min}}{\lambda_{1,\max}} \approx 1.$$ 

The following corollary of Theorem 3 considers an extreme case when $\lambda_{1,\max} = \lambda_{1,\min}$ and $\lambda_{2,\max} = 0$.

**Corollary 1:** Assume $\Omega = \{k_0, k_1, \ldots, k_{K-1}\}$. Assume each of the measurement matrices $C_k \in \mathbb{R}^{M \times N}$ is populated with i.i.d. Gaussian random entries with mean zero and variance $\frac{1}{M}$. Assume all matrices $C_k$ are generated independently of each other. Suppose $A$ has the eigendecomposition given in (9) and $U_k^T \in \mathbb{R}^{L \times N}$ ($L < N$) satisfies a scaled version of the RIP of order $S$ with isometry constant $\delta_S$ as given in (10). Assume $\lambda_{1,\max} = \lambda_{1,\min} = \lambda$ ($\lambda \neq 0$) and $\lambda_{2,\max} = 0$. Let $\nu \in (0, 1)$ denote a failure probability and $\delta \in (0, 1)$ denote a distortion factor. Define $C := \sum_{i=0}^{K-1} \lambda^{2k_i}$ and $\delta'_S := \delta_S + \delta + \delta_S \delta$. Then with probability exceeding $1 - \nu$,

$$(1 - \delta'_S)\|x_0\|_2^2 \leq \|\frac{N}{LC} C_{\Omega} x_0\|_2^2 \leq (1 + \delta'_S)\|x_0\|_2^2$$

for all $S$-sparse $x_0 \in \mathbb{R}^N$ whenever

$$MK \geq \begin{cases} 
512(1 + \delta_S)^2 \lambda^{-4(k_{k-1} - k_0)} \left(S \left(\log\left(\frac{4N}{\lambda}\right) + \log\left(\frac{N}{\lambda}\right)\right) + \log\left(\frac{2}{\nu}\right)\right) \left(1 - \delta_S\right)^2 \delta^2, & \lambda < 1 \\
512(1 + \delta_S)^2 \lambda^{4(k_{k-1} - k_0)} \left(S \left(\log\left(\frac{4N}{\lambda}\right) + \log\left(\frac{N}{\lambda}\right)\right) + \log\left(\frac{2}{\nu}\right)\right) \left(1 - \delta_S\right)^2 \delta^2, & \lambda > 1.
\end{cases}$$

**Proof** See Appendix B.

While the result of Corollary 1 is generic and valid for any $\lambda$, an important RIP result can be obtained when $\lambda = 1$. The following corollary states the result.

**Corollary 2:** Suppose the same notation and assumptions as in Corollary 1 and additionally assume $\lambda = 1$. Then with probability exceeding $1 - \nu$,

$$(1 - \delta'_S)\|x_0\|_2^2 \leq \|\frac{N}{LK} C_{\Omega} x_0\|_2^2 \leq (1 + \delta'_S)\|x_0\|_2^2$$

May 5, 2014

DRAFT
for all $S$-sparse $x_0 \in \mathbb{R}^N$ whenever

$$MK \geq \frac{512(1 + \delta_S)^2 \left( S \left( \log \left( \frac{42}{\delta_S} \right) + 1 + \log \left( \frac{N}{S} \right) \right) + \log \left( \frac{2}{\delta_S} \right) \right)}{(1 - \delta_S)^2 \delta^2}. \tag{18}$$

**Proof** See Appendix B.

These results essentially indicate that the more $\lambda$ deviates from one, the more total measurements $MK$ are required to ensure unique recovery of any $S$-sparse initial state $x_0$. The bounds on $\rho$ (which we state in Appendix B to derive Corollaries 1 and 2 from Theorem 3) also indicate that when $\lambda \neq 1$, the smallest number of measurements are required when the sample times are *consecutive* (i.e., when $k_{K-1} - k_0 = K$). Similar to what we mentioned earlier in our analysis for a scaled unitary $A$, when $\lambda \neq 1$ the effect of the initial state will be highly attenuated as we take measurements at later times (i.e., when $k_{K-1} - k_0 > K$) which results in a larger total number of measurements $MK$ sufficient for exact recovery.

### III. Concentration of Measure Inequalities and the Observability Matrix

In this section, we derive CoM inequalities for the observability matrix when the measurement matrices $C_k$ are populated with i.i.d. Gaussian random entries. These inequalities are the foundation for establishing the RIP presented in the previous section, via Lemma 1. However, they are also of independent interest for other types of problems involving the states of dynamical systems, such as detection and classification [23], [32], [33]. As mentioned earlier, we make a connection to the analysis for block diagonal matrices from Compressive Sensing (CS). To begin, note that when $\Omega = \{k_0, k_1, \ldots, k_{K-1}\}$ we can write

$$\mathcal{O}_\Omega = \begin{bmatrix}
C_{k_0} & C_{k_1} & \cdots & C_{k_{K-1}} \\
C_{k_0} & C_{k_1} & \cdots & C_{k_{K-1}} \\
& \ddots & \ddots & \ddots \\
& & \ddots & \ddots \\
& & & \ddots \end{bmatrix},$$

where $\tilde{M} := MK$ and $\tilde{N} := NK$. In this decomposition, $C_\Omega$ is a block diagonal matrix whose diagonal blocks are the measurements matrices, $C_k$. We derive CoM inequalities for two cases. We first consider the case where all measurement matrices $C_k$ are generated independently of each other. We then consider the case where all measurement matrices $C_k$ are the same.
A. Independent Random Measurement Matrices

In this section, we assume all matrices $C_k$ are generated independently of each other. Focusing just on $C_\Omega$ for the moment, we have the following bound on its concentration behavior.

**Theorem 4:** Assume each of the measurement matrices $C_k \in \mathbb{R}^{M \times N}$ is populated with i.i.d. Gaussian random entries with mean zero and variance $\frac{1}{M}$. Assume all matrices $C_k$ are generated independently of each other. Let $v_{k_0}, v_{k_1}, \ldots, v_{k_{K-1}} \in \mathbb{R}^N$ and define

$$v = \begin{bmatrix} v_{k_0}^T & v_{k_1}^T & \cdots & v_{k_{K-1}}^T \end{bmatrix}^T \in \mathbb{R}^{K N}.$$ 

Then

$$\mathbb{P}\left\{ \left\| C_\Omega v \right\|_2^2 - \| v \|_2^2 > \epsilon \| v \|_2^2 \right\} \leq \begin{cases} 2 \exp\left\{ - \frac{M \epsilon^2 \| \gamma \|_1^2}{256 \| \gamma \|_2^2} \right\}, & 0 \leq \epsilon \leq \frac{16 \| \gamma \|_2}{\| \gamma \|_\infty \| \gamma \|_1} \quad \text{(20)} \\ 2 \exp\left\{ - \frac{M \epsilon \| \gamma \|_1}{16 \| \gamma \|_\infty} \right\}, & \epsilon \geq \frac{16 \| \gamma \|_2}{\| \gamma \|_\infty \| \gamma \|_1} \quad \text{(21)} \end{cases}$$

where

$$\gamma = \gamma(v) := \begin{bmatrix} \| v_{k_0} \|_2^2 \\ \| v_{k_1} \|_2^2 \\ \vdots \\ \| v_{k_{K-1}} \|_2^2 \end{bmatrix} \in \mathbb{R}^K.$$ 

As we will be frequently concerned with applications where $\epsilon$ is small, consider the first of the cases given in the right-hand side of the above bound. (It can be shown that this case always permits any value of $\epsilon$ between 0 and $\frac{16}{\sqrt{K}}$.) Define

$$\Gamma = \Gamma(v) := \frac{\| \gamma(v) \|_1^2}{\| \gamma(v) \|_2^2} = \left( \frac{\| v_{k_0} \|_2^4 + \| v_{k_1} \|_2^4 + \cdots + \| v_{k_{K-1}} \|_2^4}{\| v_{k_0} \|_2^2 + \| v_{k_1} \|_2^2 + \cdots + \| v_{k_{K-1}} \|_2^2} \right)^2 \quad \text{(22)}$$

and note that for any $v \in \mathbb{R}^{K N}$, $1 \leq \Gamma(v) \leq K$. This simply follows from the standard relation that $\| z \|_2 \leq \| z \|_1 \leq \sqrt{K} \| z \|_2$ for all $z \in \mathbb{R}^K$. The case $\Gamma(v) = K$ is quite favorable because the failure probability will decay exponentially fast in the total number of measurements $MK$. A simple comparison between this result and the CoM inequality for a dense Gaussian matrix stated in Definition 2 reveals that we get the same degree of concentration from the $MK \times NK$ block diagonal matrix $C_\Omega$ as we

---

4All results in Section III-A may be extended to the case where the matrices $C_k$ are populated with sub-Gaussian random variables, as in [22].
would get from a dense $MK \times NK$ matrix populated with i.i.d. Gaussian random variables. This event happens if and only if the components $v_k$ have equal energy, i.e., if and only if
\[
\|v_k\|_2 = \|v_{k_1}\|_2 = \cdots = \|v_{k_{K-1}}\|_2.
\]

On the other hand, the case $\Gamma(v) = 1$ is quite unfavorable and implies that we get the same degree of concentration from the $MK \times NK$ block diagonal matrix $C_{\Omega}$ as we would get from a dense Gaussian matrix having size only $M \times NK$. This event happens if and only if $\|v_k\|_2 = 0$ for all $i \in \{0, 1, \ldots, K - 1\}$ but one $i$. Thus, more uniformity in the values of the $\|v_k\|_2$ ensures a higher probability of concentration.

We now note that, when applying the observability matrix to an initial state, we will have
\[
O_{\Omega}x_0 = C_{\Omega}A_{\Omega}x_0.
\]

This leads us to the following corollary of Theorem 4.

**Corollary 3:** Suppose the same notation and assumptions as in Theorem 4. Then for any fixed initial state $x_0 \in \mathbb{R}^N$ and for any $\epsilon \in (0, \frac{10}{\sqrt{K}})$,
\[
P\left\{ \|O_{\Omega}x_0\|_2^2 - \|A_{\Omega}x_0\|_2^2 \geq \epsilon \|A_{\Omega}x_0\|_2^2 \right\} \leq 2 \exp\left\{ -\frac{M\Gamma(A_{\Omega}x_0)\epsilon^2}{256} \right\}.
\]

There are two important phenomena to consider in this result, and both are impacted by the interaction of $A$ with $x_0$. First, on the left-hand side of (23), we see that the point of concentration of $\|O_{\Omega}x_0\|_2^2$ is around $\|A_{\Omega}x_0\|_2^2$, where
\[
\|A_{\Omega}x_0\|_2^2 = \|A^{k_0}x_0\|_2^2 + \|A^{k_1}x_0\|_2^2 + \cdots + \|A^{k_{K-1}}x_0\|_2^2.
\]

For a concentration bound of the same form as Definition 2, however, $\|O_{\Omega}x_0\|_2^2$ should concentrate around some constant multiple of $\|x_0\|_2^2$. In general, for different initial states $x_0$ and transition matrices $A$, we may see widely varying ratios $\frac{\|A_{\Omega}x_0\|_2^2}{\|x_0\|_2^2}$. However, further analysis is possible in scenarios where this ratio is predictable and fixed. Second, on the right-hand side of (23), we see that the exponent of the concentration failure probability scales with
\[
\Gamma(A_{\Omega}x_0) = \frac{\left( \|A^{k_0}x_0\|_2^2 + \|A^{k_1}x_0\|_2^2 + \cdots + \|A^{k_{K-1}}x_0\|_2^2 \right)^2}{\|A^{k_0}x_0\|_4^4 + \|A^{k_1}x_0\|_4^4 + \cdots + \|A^{k_{K-1}}x_0\|_4^4}.
\]

As mentioned earlier, $1 \leq \Gamma(A_{\Omega}x_0) \leq K$. The case $\Gamma(A_{\Omega}x_0) = K$ is quite favorable and happens when $\|A^{k_0}x_0\|_2 = \|A^{k_1}x_0\|_2 = \cdots = \|A^{k_{K-1}}x_0\|_2$; this occurs when the state “energy” is preserved over time. The case $\Gamma(A_{\Omega}x_0) = 1$ is quite unfavorable and happens when $k_0 = 0$ and $x_0 \in \text{null}(A)$ for $x_0 \neq 0$. 

May 5, 2014 DRAFT
1) Unitary and Scaled Unitary System Matrices: In the special case where $A$ is unitary (i.e., $\|A^k x\|_2^2 = \|x\|_2^2$ for all $x \in \mathbb{R}^N$ and for any power $k_i$), we can draw a particularly strong conclusion. Because a unitary $A$ guarantees both that $\|A\Omega x_0\|_2^2 = K\|x_0\|_2^2$ and that $\Gamma(A\Omega x_0) = K$, we have the following result.

**Corollary 4:** Suppose the same notation and assumptions as in Theorem 4. Assume $\Omega = \{k_0, k_1, \ldots, k_{K-1}\}$. Suppose that $A$ is a unitary operator. Then for any fixed initial state $x_0 \in \mathbb{R}^N$ and for any $\epsilon \in (0, 1)$,

$$P\left\{ \left\| \frac{1}{\sqrt{K}} \Omega x_0 \right\|_2^2 - \left\| x_0 \right\|_2^2 > \epsilon \left\| x_0 \right\|_2^2 \right\} \leq 2 \exp\left\{ -\frac{MK^2}{256} \right\}. \quad (26)$$

What this means is that we get the same degree of concentration from the $MK \times N$ matrix $\frac{1}{\sqrt{K}} \Omega \Omega$ as we would get from a fully dense $MK \times N$ matrix populated with i.i.d. Gaussian random variables. Observe that this concentration result is valid for any $x_0 \in \mathbb{R}^N$ (not necessarily sparse) and can be used, for example, to prove that finite point clouds [34] and low-dimensional manifolds [35] in $\mathbb{R}^N$ can have stable, approximate distance-preserving embeddings under the matrix $\frac{1}{\sqrt{K}} \Omega \Omega$. In each of these cases we may be able to solve very powerful signal inference and recovery problems with $MK \ll N$.

When $\Omega = \{0, 1, \ldots, K - 1\}$ (consecutive sample times), one can further derive CoM inequalities when $A$ is a scaled unitary matrix (i.e., when $A = aU$ where $a \in \mathbb{R}$ ($a \neq 1$) and $U \in \mathbb{R}^{N \times N}$ is unitary).

**Corollary 5:** Suppose the same notation and assumptions as in Theorem 4. Assume $\Omega = \{0, 1, \ldots, K - 1\}$. Suppose that $A = aU$ ($a \in \mathbb{R}$, $a \neq 0$) and $U \in \mathbb{R}^{N \times N}$ is unitary. Define $b := \Sigma_{k=0}^{K-1} a^{2k}$. Then for any fixed initial state $x_0 \in \mathbb{R}^N$ and for any $\epsilon \in (0, 1)$,

$$P\left\{ \left\| \frac{1}{\sqrt{b}} \Omega x_0 \right\|_2^2 - \left\| x_0 \right\|_2^2 > \epsilon \left\| x_0 \right\|_2^2 \right\} \leq \begin{cases} 2 \exp\left\{ -\frac{MK^2}{256 ((1 - a^2) K + a^2)} \right\}, & |a| < 1 \quad (27) \\ 2 \exp\left\{ -\frac{MK^2}{256 ((1 - a^{-2}) K + a^{-2})} \right\}, & |a| > 1 \quad (28) \end{cases}$$

5The observant reader may note that Corollary 5 requires $\epsilon$ to be less than $\frac{16}{\sqrt{K}}$. This restriction on $\epsilon$ appears so that we can focus on the upper CoM inequality [20] and ignore the lower one [21]. However, for most of the problems considered in this paper (i.e., unitary, scaled unitary, and certain symmetric matrices $A$), we can actually apply [20] for a much broader range of $\epsilon$ (up to 1 and even higher). In fact, we can show that in these settings,

$$2 \exp\{ -\frac{MK^2}{256 \|\gamma\|_2^2} \} \geq 2 \exp\{ -\frac{M\epsilon \|\gamma\|_1}{16 \|\gamma\|_\infty} \}$$

for all $\epsilon \in (0, 1)$. Consequently, we allow $\epsilon \in (0, 1)$ in Corollaries 4 and 5. We have omitted these details for the sake of space.
Proof of Corollary 5 First note that when \( A = aU \) (\( U \) is unitary) and \( \Omega = \{0, 1, \ldots, K - 1\} \) then
\[
\|A_{\Omega}x_0\|_2^2 = (1 + a^2 + \cdots + a^{2(K-1)})\|x_0\|_2^2 = b\|x_0\|_2^2. \]
From (25) when \( |a| < 1 \),
\[
\Gamma (A_{\Omega}x_0) = \frac{(1 + a^2 + \cdots + a^{2(K-1)})^2}{1 + a^4 + \cdots + a^{4(K-1)}} = \frac{(1 - a^{2K})}{(1 + a^{2K})} \frac{(1 + a^2)}{1 - a^2} = \frac{1+a^2}{1-a^2}. \quad (29)
\]
Also observe that when \( |a| < 1 \),
\[
\frac{1-a^2}{1-a^{2K}} \leq (1 - a^2) + \frac{a^2}{K}. \quad (30)
\]
Thus, from (29) and (30) and noting that \( 1 + a^2 \geq 1 + a^{2K} \) when \( |a| < 1 \),
\[
\Gamma (A_{\Omega}x_0) \geq \frac{K}{(1 - a^2)K + a^2}. \]
Similarly, one can show that when \( |a| > 1 \),
\[
\frac{1-a^{-2}}{1-a^{-2K}} \leq (1 - a^{-2}) + \frac{a^{-2}}{K} \quad (31)
\]
and consequently,
\[
\Gamma (A_{\Omega}x_0) \geq \frac{K}{(1 - a^{-2})K + a^{-2}}. \]
With the appropriate scaling of \( O_\Omega \) by \( \frac{1}{\sqrt{b}} \), the CoM inequalities follow from Corollary 3. ■

2) Implications for the RIP: As mentioned earlier, our CoM inequalities have immediate implications in establishing the RIP for the observability matrix. Based on Definition 2 and Lemma 1, in this section we prove Theorems 1 and 2.

Proof of Theorem 1 In order to establish the RIP based on Lemma 1, we simply need to evaluate \( f(\epsilon) \) in our CoM result derived in Corollary 5. One can easily verify that
\[
f(\epsilon) = \begin{cases} 
\frac{\epsilon^2}{256((1 - a^2)K + a^2)}, & |a| < 1 \\
\frac{\epsilon^2}{256((1 - a^{-2})K + a^{-2})}, & |a| > 1.
\end{cases} \quad (32)
\]
Through a union bound argument and by applying Lemma 1 for all \( \binom{N}{S} \) \( S \)-dimensional subspaces in \( \mathbb{R}^N \), the RIP result follows. ■

Proof of Theorem 2 In order to establish the RIP based on Lemma 1, we simply need to evaluate \( f(\epsilon) \) in our CoM result derived in Corollary 4. In this case,
\[
f(\epsilon) = \frac{\epsilon^2}{256}. \]

In order to prove (30), for a given \( |a| < 1 \), let \( C(a) \) be a constant such that for all \( K \) (\( K \) only takes positive integer values),
\[
\frac{1}{1-a^2K} \leq 1 + \frac{C(a)}{K}. \]
By this assumption, \( C(a) \geq \frac{K^2}{1-a^{2K}} =: g(a, K) \). Observe that for a given \( |a| < 1 \), \( g(a, K) \) is a decreasing function of \( K \) and its maximum is achieved when \( K = 1 \). Choosing \( C(a) = g(a, 1) = \frac{a^2}{1-a^2} \) completes the proof of (30).
Through a union bound argument and by applying Lemma 1 for all $N \choose S$ $S$-dimensional subspaces in $\mathbb{R}^N$, the RIP result follows.

### B. Identical Random Measurement Matrices

In this section, we consider the case where all matrices $C_k$ are identical and equal to some $M \times N$ matrix $C$ which is populated with i.i.d. Gaussian entries having zero mean and variance $\sigma^2 = 1/M$. Once again note that we can write $O_\Omega = C_\Omega A_\Omega$, where this time

$$C_\Omega := \begin{bmatrix} C_{k_0} & C_k & \cdots & C_{k_{K-1}} \\ & C & \cdots & C \end{bmatrix}, \quad (34)$$

and $A_\Omega$ is as defined in (19). The matrix $C_\Omega$ is block diagonal with equal blocks on its main diagonal, and we have the following bound on its concentration behavior.

**Theorem 5:** [22] Assume each of the measurement matrices $C_k \in \mathbb{R}^{M \times N}$ is populated with i.i.d. Gaussian random entries with mean zero and variance $\frac{1}{M}$. Assume all matrices $C_k$ are the same (i.e., $C_k = C, \forall k$). Let $v_{k_0}, v_{k_1}, \ldots, v_{k_{K-1}} \in \mathbb{R}^N$ and define

$$v = \begin{bmatrix} v_{k_0}^T & v_{k_1}^T & \cdots & v_{k_{K-1}}^T \end{bmatrix}^T \in \mathbb{R}^{KN}.$$ 

Then,

$$\mathbb{P} \left\{ \left\| C_\Omega v \right\|_2^2 - \left\| v \right\|_2^2 > \epsilon \left\| v \right\|_2^2 \right\} \leq \begin{cases} 2 \exp\left(-\frac{M\epsilon^2\left\| \lambda_1 \right\|_2^2}{256\left\| \lambda \right\|_1^2}\right), & 0 \leq \epsilon \leq \frac{16\left\| \lambda \right\|_2^2}{\left\| \lambda \right\|_{\infty}^2}, \\
2 \exp\left(-\frac{M\epsilon\left\| \lambda \right\|_1}{16\left\| \lambda \right\|_{\infty}}\right), & \epsilon \geq \frac{16\left\| \lambda \right\|_2^2}{\left\| \lambda \right\|_{\infty}^2}, \end{cases} \quad (35)$$

where

$$\lambda = \lambda(v) := \begin{bmatrix} \lambda_1 \\ \lambda_2 \\ \vdots \\ \lambda_{\min(K,N)} \end{bmatrix} \in \mathbb{R}^{\min(K,N)},$$

and $\{\lambda_1, \lambda_2, \ldots, \lambda_{\min(K,N)}\}$ are the first (non-zero) eigenvalues of the $K \times K$ matrix $V^TV$, where

$$V = \begin{bmatrix} v_{k_0} & v_{k_1} & \cdots & v_{k_{K-1}} \end{bmatrix} \in \mathbb{R}^{N \times K}.$$
Consider the first of the cases given in the right-hand side of the above bound. (This case permits any value of \( \epsilon \) between 0 and \( \frac{16}{\sqrt{\min(K,N)}} \).) Define

\[
\Lambda(v) := \frac{\|\lambda(v)\|_1^2}{\|\lambda(v)\|_2^2} \tag{36}
\]

and note that for any \( v \in \mathbb{R}^{NK} \), \( 1 \leq \Lambda(v) \leq \min(K,N) \). Moving forward, we will assume for simplicity that \( K \leq N \), although this assumption can be removed. The case \( \Lambda(v) = K \) is quite favorable and implies that we get the same degree of concentration from the \( MK \times NK \) block diagonal matrix \( C_\Omega \) as we would get from a dense \( MK \times NK \) matrix populated with i.i.d. Gaussian random variables. This event happens if and only if \( \lambda_1 = \lambda_2 = \cdots = \lambda_K \), which happens if and only if

\[
\|v_{k_1}\|_2 = \|v_{k_2}\|_2 = \cdots = \|v_{k_{K-1}}\|_2
\]

and \( \langle v_{k_i}, v_{k_\ell} \rangle = 0 \) for all \( 0 \leq i, \ell \leq K - 1 \) with \( i \neq \ell \). On the other hand, the case \( \Lambda(v) = 1 \) is quite unfavorable and implies that we get the same degree of concentration from the \( MK \times NK \) block diagonal matrix \( C_\Omega \) as we would get from a dense Gaussian matrix having only \( M \) rows. This event happens if and only if the dimension of \( \text{span}\{v_{k_1}, v_{k_2}, \ldots, v_{k_{K-1}}\} \) equals 1. Thus, comparing to Section III-A uniformity in the norms of the vectors \( v_k \) is no longer sufficient for a high probability of concentration; in addition to this we must have diversity in the directions of the \( v_{k_i} \).

The following corollary of Theorem 5 derives a CoM inequality for the observability matrix. Recall that \( O_\Omega x_0 = C_\Omega A_\Omega x_0 \) where \( C_\Omega \) is a block diagonal matrix whose diagonal blocks are repeated.

**Corollary 6:** Suppose the same notation and assumptions as in Theorem 5 and suppose \( K \leq N \). Then for any fixed initial state \( x_0 \in \mathbb{R}^N \) and for any \( \epsilon \in (0, \frac{16}{\sqrt{K}}) \),

\[
P \left\{ \frac{\|O_\Omega x_0\|_2^2 - \|A_\Omega x_0\|_2^2}{\epsilon \|A_\Omega x_0\|_2^2} > \frac{M \Lambda(A_\Omega x_0) \epsilon^2}{256} \right\} \leq 2 \exp \left\{ -\frac{256}{M \Lambda(A_\Omega x_0) \epsilon^2} \right\}. \tag{37}
\]

Once again, there are two important phenomena to consider in this result, and both are impacted by the interaction of \( A \) with \( x_0 \). First, on the left hand side of (37), we see that the point of concentration of \( \|O_\Omega x_0\|_2^2 = \|A_\Omega x_0\|_2^2 \) is around \( \|A_\Omega x_0\|_2^2 \). Second, on the right-hand side of (37), we see that the exponent of the concentration failure probability scales with \( \Lambda(A_\Omega x_0) \), which is determined by the eigenvalues of the \( K \times K \) Gram matrix \( V^T V \), where

\[
V = \begin{bmatrix} A^{k_1} x_0 & A^{k_2} x_0 & \cdots & A^{k_{K-1}} x_0 \end{bmatrix} \in \mathbb{R}^{N \times K}.
\]

As mentioned earlier, \( 1 \leq \Lambda(A_\Omega x_0) \leq K \). The case \( \Lambda(A_\Omega x_0) = K \) is quite favorable and happens when \( \|A^{k_i} x_0\|_2 = \|A^{k_\ell} x_0\|_2 = \cdots = \|A^{k_{K-1}} x_0\|_2 \) and \( \langle A^{k_i} x_0, A^{k_\ell} x_0 \rangle = 0 \) for all \( 0 \leq i, \ell \leq

May 5, 2014 DRAFT
$K - 1$ with $i \neq \ell$. The case $\Lambda(A_0 x_0) = 1$ is quite unfavorable and happens if the dimension of $\text{span}\{A^{k_0} x_0, A^{k_1} x_0, \ldots, A^{k_{K-1}} x_0\}$ equals 1.

In the special case where $A$ is unitary, we know that $\|A_0 x_0\|_2^2 = K \|x_0\|_2^2$. However, a unitary system matrix does not guarantee a favorable value for $\Lambda(A_0 x_0)$. Indeed, if $A = I_{N \times N}$ we obtain the worst case value $\Lambda(A_0 x_0) = 1$. If, on the other hand, $A$ acts as a rotation that takes a state into an orthogonal subspace, we will have a stronger result.

**Corollary 7:** Suppose the same notation and assumptions as in Theorem 5 and suppose $K \leq N$. Suppose that $A$ is a unitary operator. Suppose also that $\langle A^{k_i} x_0, A^{k_\ell} x_0 \rangle = 0$ for all $0 \leq i, \ell \leq K - 1$ with $i \neq \ell$. Then for any fixed initial state $x_0 \in \mathbb{R}^N$ and for any $\epsilon \in (0, \frac{16}{\sqrt{K}})$,

$$
\mathbb{P} \left\{ \frac{1}{\sqrt{K}} \|O_0 x_0\|_2^2 - \|x_0\|_2^2 > \epsilon \|x_0\|_2^2 \right\} \leq 2 \exp \left\{ - \frac{1}{256} \right\}.
$$

This result requires a particular relationship between $A$ and $x_0$, namely that $\langle A^{k_i} x_0, A^{k_\ell} x_0 \rangle = 0$ for all $0 \leq i, \ell \leq K - 1$ with $i \neq \ell$. Thus, given a particular system matrix $A$, it is possible that it might hold for some $x_0$ and not others. One must therefore be cautious in using this concentration result for CS applications (such as proving the RIP) that involve applying the concentration bound to a prescribed collection of vectors [14]; one must ensure that the “orthogonal rotation” property holds for each vector in the prescribed set.

**IV. Case Study: Estimating the Initial State in a Diffusion Process**

So far we have provided theorems that provide a sufficient number of measurements for stable recovery of a sparse initial state under certain conditions on the state transition matrix and under the assumption that the measurement matrices are independent and populated with random entries. In this section, we use a case study to illustrate some of the phenomena raised in the previous sections.

**A. System Model**

We consider the problem of estimating the initial state of a system governed by the diffusion equation

$$\frac{\partial x}{\partial t} = \nabla \cdot (D(p) \nabla x(p,t)),$$

where $x(p,t)$ is the concentration, or density, at position $p$ at time $t$, and $D(p)$ is the diffusion coefficient at position $p$. If $D$ is independent of position, then this simplifies to

$$\frac{\partial x}{\partial t} = D \nabla^2 x(p,t).$$
The boundary conditions can vary according to the surroundings of the domain \( \Pi \). If \( \Pi \) is bounded by an impermeable surface (e.g., a lake surrounded by the shore), then the boundary conditions are

\[
n(p) \cdot \frac{\partial x}{\partial n} \bigg|_{p \in \partial \Pi} = 0,
\]

where \( n(p) \) is the normal to \( \partial \Pi \) at \( p \). We will work with an approximate model discretized in time and in space. For simplicity, we explain a one-dimensional (one spatial dimension) diffusion process here but a similar approach of discretization can be taken for a diffusion process with two or three spatial dimensions. Let \( \mathbf{p} := \begin{bmatrix} p(1) & p(2) & \cdots & p(N) \end{bmatrix}^T \) be a vector of equally-spaced locations with spacing \( \Delta_s \), and let \( \mathbf{x}(p,t) := \begin{bmatrix} x(p(1),t) & x(p(2),t) & \cdots & x(p(N),t) \end{bmatrix}^T \). Then a first difference approximation in space gives the model

\[
\dot{x}(p,t) = Gx(p,t),
\]

where \( G \) represents the discrete Laplacian. We have

\[
G = -F = \frac{D}{\Delta_s^2} \begin{bmatrix}
-1 & 1 & 0 & 0 & \cdots & 0 \\
1 & -2 & 1 & 0 & \cdots & 0 \\
0 & 1 & -2 & 1 & \cdots & 0 \\
\vdots & \ddots & \ddots & \ddots & \ddots & \ddots \\
0 & \cdots & 1 & -1
\end{bmatrix},
\]

where \( F \) is the Laplacian matrix associated with a path (one spatial dimension). This discrete Laplacian \( G \) has eigenvalues \( \lambda_i = -\frac{2D}{\Delta_s^2} \left( 1 - \cos \left( \frac{\pi}{N} (i-1) \right) \right) \) for \( i = 1, 2, \ldots, N \).

To obtain a discrete-time model, we choose a sampling time \( T_s \) and let the vector \( \mathbf{x}_k = \mathbf{x}(p,kT_s) \) be the concentration at positions \( p(1), p(2), \ldots, p(N) \) at sampling time \( k \). Using a first difference approximation in time, we have

\[
\mathbf{x}_k = A\mathbf{x}_{k-1},
\]

where \( A = I_N + GT_s \). For a diffusion process with two spatial dimensions, a similar analysis would follow, except one would use the Laplacian matrix of a grid (instead of the Laplacian matrix of a one-dimensional path) in \( A = I_N + GT_s \). For all simulations in this section we take \( D = 1, \Delta_s = 1, N = 100, \) and \( T_s = 0.1 \). An example simulation of a one-dimensional diffusion is shown in Figure 1, where we have initialized the system with a sparse initial state \( \mathbf{x}_0 \) containing unit impulses at \( S = 10 \) randomly chosen locations.

In Section IV-C we provide several simulations which demonstrate that recovery of a sparse initial state is possible from compressive measurements.
Fig. 1: One-dimensional diffusion process. At time zero, the concentration (the state) is non-zero only at a few locations of the path graph of $N = 100$ nodes.

**B. Diffusion and its Connections to Theorem 3**

Before presenting the recovery results from compressive measurements, we would like to mention that our analysis in Theorem 3 gives some insight into (but is not precisely applicable to) the diffusion problem. In particular, the discrete Laplacian matrix $G$ and the corresponding state transition matrix $A$ (see below) are almost circulant, and so their eigenvectors will closely resemble the DFT basis vectors. The largest eigenvalues correspond to the lowest frequencies, and so the $U_1$ matrix corresponding to $G$ or $A$ will resemble a basis of the lowest frequency DFT vectors. While such a matrix does not technically satisfy the RIP, matrices formed from random sets of DFT vectors do satisfy the RIP with high probability [31]. Thus, even though we cannot apply Theorem 3 directly to the diffusion problem, it does provide some intuition that sparse recovery should be possible in the diffusion setting.

**C. State Recovery From Compressive Measurements**

In this section, we consider a two-dimensional diffusion process. As mentioned earlier, the state transition matrix $A$ associated with this process is of the form $A = I_N + G T_s$, where $T_s$ is the sampling time and $G$ is the Laplacian matrix of a grid. In these simulations, we consider a grid of size $10 \times 10$ with $T_s = 0.1$.

We also consider two types of measuring processes. We first look at random measurement matrices
Fig. 2: Dense Measurements versus Line Measurements. The color of a node indicates the corresponding weight of that node. The darker the node color, the higher the weight. These weights are the entries of each row of each $C_k$. (a) Dense Measurements. The weights are drawn from a Gaussian distribution with mean zero and variance $\frac{1}{M}$. These values are random and change for each measurement. (b) Line Measurements. The weights are generated as a function of the perpendicular distances of all nodes of the grid to the line. The slope and the intercept of the line are random and change for each measurement. $C_k \in \mathbb{R}^{M \times N}$ where the entries of each matrix are i.i.d. Gaussian random variables with mean zero and variance $\frac{1}{M}$. Note that this type of measurement matrix falls within the assumptions of our theorems in Sections II and III-A. In this measuring scenario, all of the nodes of the grid (i.e., all of the states) will be measured at each sample time. Formally, at each observation time we record a random linear combination of all nodes. In the following, we refer to such measurements as “Dense Measurements.” Figure 2(a) illustrates an example of how the random weights are spread over the grid. The weights (the entries of each row of each $C_k$) are shown using grayscale. The darker the node color, the higher the corresponding weight. We also consider a more practical measuring process in which at each sample time the operator measures the nodes of the grid occurring along a line with random slope and random intercept. Formally, $C_k(i, j) = \exp \left( -\frac{d_k(i,j)}{c} \right)$ where $d_k(i,j)$ is the perpendicular distance of node $j$ ($j = 1, \ldots, N$) to the $i$th ($i = 1, \ldots, M$) line with random slope and random intercept and $c$ is an
absolute constant that determines how fast the node weights decrease as their distances increase from the line. Figure 2(b) illustrates an example of how the weights are spread over the grid in this scenario. Observe that the nodes that are closer to the line are darker, indicating higher weights for those nodes. We refer to such measurements as “Line Measurements.”

To address the problem of recovering the initial state $x_0$, let us first consider the situation where we collect measurements only of $x_0 \in \mathbb{R}^{100}$ itself. We fix the sparsity level of $x_0$ to $S = 9$. For various values of $M$, we construct measurement matrices $C_0$ according to the two models explained above. At each trial, we collect the measurements $y_0 = C_0 x_0$ and attempt to recover $x_0$ given $y_0$ and $C_0$ using the canonical $\ell_1$-minimization problem from CS:

$$\hat{x}_0 = \arg \min_{x \in \mathbb{R}^N} \|x\|_1 \text{ subject to } y_k = C_k A^k x$$

(40)

with $k = 0$. (In the next paragraph, we repeat this experiment for different $k$.) In order to imitate what might happen in reality (e.g., a drop of poison being introduced to a lake of water at $k = 0$), we assume the initial contaminant appears in a cluster of nodes on the associated diffusion grid. In our simulations, we assume the $S = 9$ non-zero entries of the initial state correspond to a $3 \times 3$ square-neighborhood of nodes on the grid. For each $M$, we repeat the recovery problem for 300 trials; in each trial we generate a random sparse initial state $x_0$ (an initial state with a random location of the $3 \times 3$ square and random values of the 9 non-zero entries) and a measurement matrix $C_0$ as explained above.

Figure 3(a) depicts, as a function of $M$, the percent of trials (with $x_0$ and $C_0$ randomly chosen in each trial) in which the initial state is recovered perfectly, i.e., $\hat{x}_0 = x_0$. Naturally, we see that as we take more measurements, the recovery rate increases. When Line Measurements are taken, with almost 35 measurements we recover every sparse initial state of dimension 100 with sparsity level 9. When Dense Measurements are employed, however, we observe a slightly weaker recovery performance at $k = 0$ as almost 45 measurements are required to see exact recovery. In order to see how the diffusion phenomenon affects the recovery, we repeat the same experiment at $k = 10$. In other words, we collect the measurements $y_{10} = C_{10} x_{10} = C_{10} A^{10} x_0$ and attempt to recover $x_0$ given $y_{10}$ and $C_{10} A^{10}$ using the canonical $\ell_1$-minimization problem (40). As shown in Fig. 3(b), the recovery performance is improved when Line and Dense Measurements are employed (with almost 25 measurements exact recovery is possible). Qualitatively, this suggests that due to diffusion, at $k = 10$, the initial contaminant is now propagating and consequently a larger surface of the lake (corresponding to more nodes of the grid) is contaminated. In this situation, a higher number of contaminated nodes will be measured by Line Measurements which potentially can improve the recovery performance of the initial state.
Fig. 3: Signal recovery from compressive measurements of a diffusion process which has initiated from a sparse initial state of dimension $N = 100$ and sparsity level $S = 9$. The plots show the percent of trials (out of 300 trials in total) with perfect recovery of the initial state $x_0$ versus the number of measurements $M$. (a) Recovery from compressive measurements at time $k = 0$. (b) Recovery from compressive measurements at time $k = 10$.

In order to see how the recovery performance would change as we take measurements at different times, we repeat the previous example for $k = \{0, 1, 2, 8, 50, 100\}$. The results are shown in Fig. 4(a) and Fig. 4(b) for Dense and Line Measurements, respectively. In both cases, the recovery performance starts to improve as we take measurements at later times. However, in both measuring scenarios, the recovery performance tends to decrease if we wait too long to take measurements. For example, as shown in Fig. 4(a), the recovery performance is significantly decreased at time $k = 100$ when Dense Measurements are employed. A more dramatic decrease in the recovery performance can be observed when Line Measurements are employed in Fig. 4(b). Again this behavior is as expected and can be interpreted with the diffusion phenomenon. If we wait too long to take measurements from the field of study (e.g., the lake of water), the effect of the initial contaminant starts to disappear in the field (due to diffusion) and consequently measurements at later times contain less information. In summary, one could conclude from these observations that taking compressive measurements of a diffusion process at times that are too early or too late might decrease the recovery performance.

In another example, we fix $M = 32$, consider the same model for the sparse initial states with $S = 9$ as in the previous examples, introduce white noise in the measurements with standard deviation 0.05,
Fig. 4: Signal recovery from compressive measurements of a diffusion process which has initiated from a sparse initial state of dimension \(N = 100\) and sparsity level \(S = 9\). The plots show the percent of trials (out of 300 trials in total) with perfect recovery of the initial state \(x_0\) versus the number of measurements \(M\) taken at observation times \(k = \{0, 1, 2, 8, 50, 100\}\). (a) Recovery from compressive Dense Measurements. (b) Recovery from compressive Line Measurements.

use a noise-aware version of the \(\ell_1\) recovery algorithm [13], and plot a histogram of the recovery errors \(\|\hat{x}_0 - x_0\|_2\). We perform this experiment at \(k = 2\) and \(k = 10\). As can be seen in Fig. 5(a) at time \(k = 2\) the Dense Measurements have lower recovery errors (almost half) compared to the Line Measurements. However, if we take measurements at time \(k = 10\), the recovery error of both measurement processes tends to be similar, as depicted in Fig. 5(b).

Of course, it is not necessary to take all of the measurements only at one observation time. What may not be obvious a priori is how spreading the measurements over time may impact the initial state recovery. To this end, we perform the signal recovery experiments when a total of \(MK = 32\) measurements are spread over \(K = 4\) observation times (at each observation time we take \(M = 8\) measurements). In order to see how different observation times affect the recovery performance, we repeat the experiment for different sample sets, \(\Omega_i\). We consider 10 sample sets as \(\Omega_1 = \{0, 1, 2, 3\}\), \(\Omega_2 = \{4, 5, 6, 7\}\), \(\Omega_3 = \{8, 9, 10, 11\}\), \(\Omega_4 = \{10, 20, 30, 40\}\), \(\Omega_5 = \{20, 21, 22, 23\}\), \(\Omega_6 = \{10, 30, 50, 70\}\), \(\Omega_7 = \{51, 52, 53, 54\}\), \(\Omega_8 = \{60, 70, 80, 90\}\), \(\Omega_9 = \{91, 92, 93, 94\}\), and \(\Omega_{10} = \{97, 98, 99, 100\}\). Figure 6(a) illustrates the results. For both of the measuring scenarios, the overall recovery performance improves when we take
Fig. 5: Signal recovery from $M = 32$ compressive measurements of a diffusion process which has initiated from a sparse initial state of dimension $N = 100$ and sparsity level $S = 9$. The plots show the recovery error of the initial state $\|e\|_2 = \|\hat{x}_0 - x_0\|_2$ over 300 trials. (a) Recovery from compressive measurements at time $k = 2$. (b) Recovery from compressive measurements at time $k = 10$.

measurements at later times. As mentioned earlier, however, if we wait too long to take measurements the recovery performance drops. For sample sets $\Omega_2$ through $\Omega_6$, we have perfect recovery of the initial state only from $MK = 32$ total measurements, either using Dense or Line Measurements. The overall recovery performance is not much different compared to, say, taking $M = 32$ measurements at a single instant and so there is no significant penalty that one pays by slightly spreading out the measurement collection process in time, as long as a different random measurement matrix is used at each sample time. We repeat the same experiment when the measurements are noisy. We introduce white noise in the measurements with standard deviation 0.05 and use a noise-aware version of the $\ell_1$-minimization problem to recover the true solution. Figure 6(b) depicts a histogram of the recovery errors $\|\hat{x}_0 - x_0\|_2$ when $MK = 32$ measurements are spread over $K = 4$ sample times $\Omega_4 = \{10, 20, 30, 40\}$.

APPENDIX

A. Proof of Theorem 3

We start the analysis by showing that $\|A_{\Omega}x_0\|_2^2$ lies within a small neighborhood around $\|x_0\|_2^2$ for any $S$-sparse $x_0 \in \mathbb{R}^N$. To this end, we derive the following lemma.

\textbf{Lemma 2:} Assume $\Omega = \{k_0, k_1, \ldots, k_{K-1}\}$. Assume $A$ has the eigendecomposition given in (9) and $U_1^T \in \mathbb{R}^{L \times N}$ ($L < N$) satisfies a scaled version of the RIP of order $S$ with isometry constant $\delta_S$ as given in (10). Then, for $\delta_S \in (0, 1)$,

\[(1 - \delta_S) \frac{L}{N} \sum_{i=0}^{K-1} \lambda_{2,\min}^{2k_i} \leq \frac{\|A_{\Omega}x_0\|_2^2}{\|x_0\|_2^2} \leq (1 + \delta_S) \frac{L}{N} \sum_{i=0}^{K-1} \lambda_{1,\max}^{2k_i} + \sum_{i=0}^{K-1} \lambda_{2,\max}^{2k_i} \quad (41)\]

holds for all $S$-sparse $x_0 \in \mathbb{R}^N$.

\textbf{Proof of Lemma 2} If $A$ is of the form given in (9), we have $Ax_0 = U_1 A_1 U_1^T x_0 + U_2 A_2 U_2^T x_0$, and consequently,

$\|Ax_0\|_2^2 = x_0^T U_1 A_1^2 U_1^T x_0 + x_0^T U_2 A_2^2 U_2^T x_0 \geq \|A_1 U_1^T x_0\|_2^2 \geq \lambda_{1,\min}^2 \|U_1^T x_0\|_2^2$. 

May 5, 2014 DRAFT
On the other hand,
\[ \|Ax_0\|_2^2 = x_0^T U_1 \Lambda_1^2 U_1^T x_0 + x_0^T U_2 \Lambda_2^2 U_2^T x_0 \leq \lambda_{1,\max}^2 \|U_1^T x_0\|_2^2 + \lambda_{2,\max}^2 \|U_2^T x_0\|_2^2 \]
\[ \leq \lambda_{1,\max}^2 \|U_1^T x_0\|_2^2 + \lambda_{2,\max}^2 \|x_0\|_2^2. \]

Thus,
\[ \lambda_{2,\min}^2 \|U_1^T x_0\|_2^2 \leq \|Ax_0\|_2^2 \leq \lambda_{1,\max}^2 \|U_1^T x_0\|_2^2 + \lambda_{2,\max}^2 \|x_0\|_2^2. \] (42)

If \( U_1^T \) satisfies the scaled RIP, then from (10) and (42) for \( \delta_S \in (0, 1) \),
\[ (1 - \delta_S) \frac{L}{N} \lambda_{1,\min}^{2k_i} \leq \frac{\|A^{k_i} x_0\|_2^2}{\|x_0\|_2^2} \leq (1 + \delta_S) \frac{L}{N} \lambda_{1,\max}^{2k_i} + \lambda_{2,\max}^{2k_i} \] (43)
holds for all \( S \)-sparse \( x_0 \in \mathbb{R}^N \). Similarly, one can show that for \( i \in \{0, 1, \ldots, K - 1\} \),
\[ \lambda_{1,\max}^{2k_i} \|U_1^T x_0\|_2^2 \leq \|A^{k_i} x_0\|_2^2 \leq \lambda_{1,\max}^{2k_i} \|U_1^T x_0\|_2^2 + \lambda_{2,\max}^{2k_i} \|x_0\|_2^2, \]
and consequently, for \( \delta_S \in (0, 1) \),
\[ (1 - \delta_S) \frac{L}{N} \sum_{i=0}^{K-1} \lambda_{1,\min}^{2k_i} \leq \frac{\|A^{k_i} x_0\|_2^2}{\|x_0\|_2^2} \leq (1 + \delta_S) \frac{L}{N} \sum_{i=0}^{K-1} \lambda_{1,\max}^{2k_i} + \sum_{i=0}^{K-1} \lambda_{2,\max}^{2k_i} \] (44)
holds for all \( S \)-sparse \( x_0 \in \mathbb{R}^N \). Consequently using (24), for \( \delta_S \in (0, 1) \),
\[ (1 - \delta_S) \frac{L}{N} \sum_{i=0}^{K-1} \lambda_{1,\min}^{2k_i} \leq \frac{\|A_{\Omega} x_0\|_2^2}{\|x_0\|_2^2} \leq (1 + \delta_S) \frac{L}{N} \sum_{i=0}^{K-1} \lambda_{1,\max}^{2k_i} + \sum_{i=0}^{K-1} \lambda_{2,\max}^{2k_i} \]
holds for all \( S \)-sparse \( x_0 \in \mathbb{R}^N \). \[ \square \]

Lemma 2 provides deterministic bounds on the ratio \( \frac{\|A_{\Omega} x_0\|_2^2}{\|x_0\|_2^2} \) for all \( S \)-sparse \( x_0 \) when \( U_1^T \) satisfies the scaled RIP. Using this deterministic result, we can now state the proof of Theorem 3 where we show that a scaled version of \( C_{\Omega} \) satisfies the RIP with high probability.

First observe that when all matrices \( C_k \) are independent and populated with i.i.d. Gaussian random entries, from Corollary 3 we have the following CoM inequality for \( C_{\Omega} \). For any fixed \( S \)-sparse \( x_0 \in \mathbb{R}^N \), let \( v = A_{\Omega} x_0 \in \mathbb{R}^{NK} \). Then for any \( \epsilon \in (0, \frac{16}{\sqrt{R}}) \),
\[ \mathbb{P} \left\{ \left\| C_{\Omega} v \right\|_2^2 - \|v\|_2^2 > \epsilon \|v\|_2^2 \right\} \leq 2 \exp \left\{ - \frac{M \Gamma(v) \epsilon^2}{256} \right\}. \] (45)
As can be seen, the right-hand side of (45) is signal dependent. However, we need a universal failure probability bound (that is independent of \( x_0 \)) in order to prove the RIP based a CoM inequality. Define
\[ \rho := \inf_{S \text{-sparse } x_0 \in \mathbb{R}^N} \Gamma(A_{\Omega} x_0). \] (46)
Therefore from (45) and (46), for any fixed \( S \)-sparse \( x_0 \in \mathbb{R}^N \) and for any \( \epsilon \in (0, \frac{16}{\sqrt{R}}) \),
\[ \mathbb{P} \left\{ \left| \|C_{\Omega} A_{\Omega} x_0\|_2^2 - \|A_{\Omega} x_0\|_2^2 \right| > \epsilon \|A_{\Omega} x_0\|_2^2 \right\} \leq 2 \exp \left\{ - \frac{M \rho \epsilon^2}{256} \right\} = 2 \exp \left\{ - \tilde{M} f(\epsilon) \right\}, \] (47)
where \( f(\epsilon) := \frac{\rho^2}{256K^2} \), \( \bar{M} := MK \), and \( \bar{N} := NK \). Let \( \nu \in (0,1) \) denote a failure probability and \( \delta \in (0, \frac{16}{\sqrt{K}}) \) denote a distortion factor. Through a union bound argument and by applying Lemma 1 for all \( \binom{N}{S} \) \( S \)-dimensional subspaces in \( \mathbb{R}^N \), whenever \( C_\Omega \in \mathbb{R}^{\bar{M} \times \bar{N}} \) satisfies the CoM inequality (47) with
\[
MK \geq \frac{S \log(\frac{42}{\delta}) + \log(\frac{\delta}{S}) + \log(\binom{N}{S})}{f(\frac{\delta}{\sqrt{2}})},
\]
then with probability exceeding \( 1 - \nu \),
\[
(1 - \delta)\|A_\Omega x_0\|^2 \leq \|C_\Omega A_\Omega x_0\|^2 \leq (1 + \delta)\|A_\Omega x_0\|^2,
\]
for all \( S \)-sparse \( x_0 \in \mathbb{R}^N \). Consequently using the deterministic bound on \( \|A_\Omega x_0\|^2 \) derived in (41), with probability exceeding \( 1 - \nu \),
\[
(1 - \delta) \left( (1 - \delta_S) \frac{1}{N} \sum_{i=0}^{K-1} \lambda_{1,\min}^{2k_i} \right) \leq \frac{\|O_{\Omega} x_0\|^2}{\|x_0\|^2} \leq (1 + \delta) \left( 1 + \frac{1}{N} \sum_{i=0}^{K-1} \lambda_{1,\max}^{2k_i} + \sum_{i=0}^{K-1} \lambda_{2,\max}^{2k_i} \right)
\]
for all \( S \)-sparse \( x_0 \in \mathbb{R}^N \). \( \square \)

### B. Proof of Corollary 1 and Corollary 2

We simply need to derive a lower bound on \( \Gamma(A_\Omega x_0) \) as an evaluation of \( \rho \). Recall (25) and define
\[
z_0 := \left[ \|A^{k_0} x_0\|^2 \|A^{k_1} x_0\|^2 \cdots \|A^{k_{K-1}} x_0\|^2 \right]^T \in \mathbb{R}^K.
\]
If all the entries of \( z_0 \) lie within some bounds as \( \ell_\ell \leq z_0 (i) \leq \ell_h \) for all \( i \), then one can show that
\[
\Gamma(A_\Omega x_0) \geq K \left( \frac{\ell_\ell}{\ell_h} \right)^2.
\]
Using the deterministic bound derived in (44) on \( \|A^{k_i} x_0\|^2 \) for all \( i \in \{0,1,\ldots,K-1\} \), one can show that when \( \lambda = 1 \) \( (\lambda_{1,\max} = \lambda_{1,\min} = \lambda \) and \( \lambda_{2,\max} = 0) \), \( \ell_\ell = (1 - \delta_S) \frac{1}{N} \|x_0\|^2 \) and \( \ell_h = (1 + \delta_S) \frac{1}{N} \|x_0\|^2 \), and thus,
\[
\rho \geq K \left( \frac{1 - \delta_S}{1 + \delta_S} \right)^2.
\]
Similarly one can show that when \( \lambda < 1 \),
\[
\rho \geq K \left( \frac{1 - \delta_S}{1 + \delta_S} \right)^2 \lambda^{4(k_{K-1} - k_0)},
\]
and when \( \lambda > 1 \),
\[
\rho \geq K \left( \frac{1 - \delta_S}{1 + \delta_S} \right)^2 \lambda^{-4(k_{K-1} - k_0)}.
\]
Using these lower bounds on \( \rho \) (recall that \( \rho \) is defined in (46) as the infimum of \( \Gamma(A_\Omega x_0) \) over all \( S \)-sparse \( x_0 \in \mathbb{R}^N \)) in the result of Theorem 3 completes the proof. We also note that when \( \lambda_{1,\max} = \)}
\( \lambda_{1,\min} = \lambda \) and \( \lambda_{2,\max} = 0 \), the upper bound given in (47) can be used to bound the left-hand side failure probability even when \( \epsilon \geq \frac{16}{\sqrt{K}} \). In fact, we can show that (47) holds for any \( \epsilon \in (0, 1) \). The RIP results of Corollaries 1 and 2 follow based on this CoM inequality. We have omitted these details for the sake of space.
