Intrinsic photometric characterisation of stellar oscillations and granulation

Solar reference values and CoRoT response functions

ABSTRACT

Context. Measuring amplitudes of solar-like oscillations and the granulation power spectral density constitute two promising sources of information to improve our understanding and description of the convection in outer layers of stars. However, different instruments, using different techniques and different band passes, bring measurements which cannot be directly compared neither to each other nor to theoretical values.

Aims. In this work, we define simple response functions to derive intrinsic oscillation amplitudes and granulation power density, from photometry measurements obtained with a specific instrument on a specific star.

Methods. We test this method on different photometry data sets obtained on the Sun with two different instruments in three different band passes.

Results. We show that the results are in good agreement and we establish reference intrinsic values for the Sun in photometry. We also compute the response functions of the CoRoT instrument for a range of parameters representative of the Main Sequence solar-like pulsators to be observed with CoRoT. We show that these response functions can be conveniently described by simple analytic functions of the effective temperature of the target stars.

Key words. Sun: oscillations – Sun: granulation – Stars: oscillations – Techniques: photometric – Convection

1. Introduction

Solar-like oscillations are being detected in a rapidly growing number of stars (see e.g. Bedding & Kjeldsen 2007). The excitation of these oscillations first observed in the Sun is attributed to the acoustic noise generated by convection in the outer layers of stars and the measurement of their amplitude is a source of information on the convection process (see e.g. Samadi et al. 2007a,b). The existing theoretical works generally bring parametric scaling laws calibrated on the Sun. However, as noticed by Kjeldsen et al. (2005), measurements made on different stars with different instruments using different techniques in velocimetry or photometry, in different spectral lines or band passes, have different sensitivity to the oscillations. They cannot be compared directly to each other, nor to theoretical values. The comparison to the Sun is not straightforward either, since the different existing data sets obtained on the Sun have not been translated into a proper standard reference suited for comparison with stars. Kjeldsen et al. (2005) initiated such a normalization work and a comparison between several stars. Then, very recently, Kjeldsen et al. (2008) measured the solar oscillation amplitude with stellar techniques, aiming at setting up a consistent reference for stellar oscillation measurements. This was done in velocimetry, since till now the vast majority of solar-like oscillations measured in other stars has been obtained with this technique. However, CoRoT (Baglin et al. 2006) has started bringing photometric measurements of oscillation in solar-like pulsators which will need to be measured quantitatively and compared with those of the Sun and with those obtained in velocimetry. In addition to oscillations, rapid photometry might allow measuring, in approximately the same domain of frequency, the power density spectrum contribution associated with the stellar granulation. Granulation being a manifestation of the convective motions at the photosphere level, the profile of its power density spectrum is expected to reflect characteristic time scales and geometrical scales associated with the convection process as described by heavy 3D numerical simulations (see e.g. Ludwig 2006; Trampedach et al. 1998) or by parametrized models (see e.g. Baudin et al. 2007).

In the present work, we consider measurements of solar photometrical variations obtained with two different instruments in four different band passes (SOHO/VIRGO/PMO6 and SPM three channels). In the corresponding instrumental power density spectra, we fit contributions from the solar background and from the acoustic oscillations (Sect.2). Then, in Sect.3, we establish a simple instrumental response function relating the instrumental power density measurement to the intrinsic bolometric luminosity relative variation. These response functions can be applied to infer intrinsic (bolometric) power density of solar background from specific photometry measurements. They also can be used to derive intrinsic amplitude of solar radial oscillations from the same data. We discuss how they can be
adapted for non radial modes. Following Kjeldsen et al. (2005) and Kjeldsen et al. (2008), we also propose to relate the oscillation mean power density measurement to an intrinsic amplitude chosen here to be the bolometric amplitude for radial modes. In Sect.4, we show that the results obtained with the different data sets considered here are consistent to a good approximation and allow us to produce a reference value of bolometric radial oscillation amplitude for the Sun observed as a star, and a reference bolometric power density spectrum for Solar granulation. Then (Sect.5), we compute the response functions adapted to the CoRoT instrument for stars representative of potential solar-like pulsators on the Main Sequence in terms of effective temperatures, log g values and chemical compositions. We show that to a great extent, the dependency with log g and chemical composition can be neglected and that the CoRoT response functions can be conveniently described with a good precision by analytic functions of $T_{\text{eff}}$.

2. Observational material and power density spectra

We consider four data sets obtained on the Sun with different techniques and different band pass by SOHO/VIRGO/PMO6 (essentially bolometric variations) and by SOHO/VIRGO/SPM (photon counting) in three narrow (5nm) bands at 402nm (blue), 500nm (green) and 862nm (red) (Frohlich et al. 1997). For each of these time series, we compute the power density spectrum shown in Fig 1 and Fig 2. Following the technique proposed by Kjeldsen et al. (2005) for stellar oscillations measurements, we smooth these spectra with a boxcar of width 405 μHz corresponding to 3 times the solar large separation (135 μHz).

Then, we perform a least square fit of each spectrum with three components: a flat white noise contribution essentially due to photon counting noise, the solar background contribution detailed hereafter, and on top, the stellar oscillation spectrum contribution. For the solar background contribution, following Harvey (1985) and Andersen et al. (1998a), we consider a sum of powerlaws: $P(\nu) = \sum P_i(\nu)$, and $P_i(\nu) = a_i \nu^{2} \tau_i/(1 + (2\pi\nu)^{2})$ (also noted $P_i(\nu) = A_i/(1 + (B_i\nu)^2)$ for convenience hereafter), with $\nu$ the frequency, $\tau_i$ the characteristic time scale and $C_i$ the slope at high frequency associated with each powerlaw, and $a_i$ a normalizing factor such as: $\nu^2 = \int P_i(\nu) d\nu$ corresponds to the variance of the corresponding time series. Note that in the case of Harvey (1985), $C_i$ being set to 2, $a_i = 2$. This corresponds to a signal which autocorrelation in time has a decreasing exponential behaviour. However, as mentioned by Harvey (1985), other values for decay rate power of time might be found for different type of data probing the atmosphere at different heights (see e.g. Andersen et al. 1998a).

The physical processes most commonly considered in the solar background and represented by such powerlaws are: activity (predominant up to $\sim 10 \mu Hz$), supergranulation (up to $\sim 100 \mu Hz$), mesogranulation (up to $\sim 1 \text{mHz}$), and granulation (see e.g. Andersen et al. 1998b, Anklin et al. 1998, Aigrain et al. 2003). In the present study, we will focus on the two latter processes showing significant contribution above 100 μHz, in the frequency domain where oscillations are found.

An estimate of the two first contributions (white noise and solar background) is obtained by a simultaneous fit of the spectrum outside the domain where the oscillation signal is seen with function $D + \sum P_i(\nu)$, where $D$ represents the white noise contribution. After subtraction of these two components, we isolate the one due to stellar oscillations.

The two powerlaw components (7 parameters: $A_i, B_i, C_i$, and $D$) give satisfactory fit of the background for our purpose and we do not find necessary to include other components like supergranulation or activity.

As shown by error values in Tab. 1, the fit give satisfactory results in the case of SPM data, especially for the blue and green channels. In the case of SPM/red channel, the coefficients are obtained with very large error bars and in the case of PMO6, the convergence precision is even worse, due to the larger white noise component. We note that these fits all suggest a value $C_i$ around 4, in agreement with the results obtained by Andersen et al. (1998a). We thus decided to fit again the previous function, but forcing the $C_i$ coefficients to the value 4, thus reducing the number of free parameters to 5 and obtaining more precise determination of them.

The results shown in Fig. 2(see also Tab. 2) are very satisfactory, and we will refer to these values hereafter.

As could be expected, the level of the intensity components ($A_1$ and $A_2$) attributed to granulation and mesogranulation is very different in the measurements associated to different techniques and different band passes (see Fig. 3 top). The same is true for the contribution associated with the oscillations (Fig. 3 bottom), stressing the necessity to establish a reference indepen-
Table 1. Fit with seven parameters. Values of the parameters are given as well as the associated one-sigma error estimates.

3. Instrumental response functions

In this section we establish a relation between intensity variation observed with a given instrument (hereafter ‘instrumental flux variation’) and an intrinsic quantity defined as the ‘bolometric luminosity variation’. This relation features a response function characteristic of the instrument.

We derive the response function for an individual non-radial mode (Sect. 3.2), then for a smoothed power density spectrum (Sect. 3.3), and finally for the granulation (Sect. 3.4).

This is done taking into account both the band-width of the instrument, the spectral energy distribution of the given star (approximated by a black body law) and the dependence of the stellar limb-darkening with the wavelength (given by stellar atmosphere models).

3.1. Instrumental flux variation and local temperature variation

Here, we express the relative instrumental flux variation $\delta I/I$ as a function of the local relative variation of the temperature at the stellar photosphere $\delta T(\theta, \phi)/T$.

First we define the relative variation of the instrumental flux $I$:

$$\left(\frac{\delta I}{I}\right)(t) = \frac{\int_{\lambda} d\lambda E(\lambda) \delta F_\lambda}{\int_{\lambda} d\lambda E(\lambda) F_\lambda}$$

where $E(\lambda)$ is the global efficiency in terms of energy of the instrument at the wavelength $\lambda$, $F_\lambda$ the flux received from the star at the wavelength $\lambda$ and $\delta F_\lambda$ its variation.

Then, following the approach of Berthomieu & Provost (1990), we show (see Appendix A) that $F_\lambda$ and $\delta F_\lambda$ can be approximated as

$$F_\lambda = 2\pi H_\lambda G_\lambda B_\lambda$$

where $B_\lambda$ is the black body law evaluated at the photosphere, i.e. at $T = T_{\text{eff}}$ and where we have defined

$$H_\lambda \equiv 2 \left(\int_{\mu} d\mu g_\lambda(\mu)\right)^{-1}$$
variation' \( \langle \delta L/L \rangle_{\ell m} \), defined as an extension of the specific case of radial modes where \( \langle \delta L/L \rangle = 48 T_{\text{eff}}/T_{\text{eff}} \).

As detailed in Appendix A, we consider the relative temperature fluctuations associated with a mode with degree \( \ell \) and azimuthal order \( m \):

\[
\left( \frac{\delta T}{T} \right)(t, \theta, \phi) = \Theta_{\ell m}(t) Y_{\ell m}^m(\theta', \phi')
\]

where \( \Theta_{\ell m}(t) \) is the intrinsic and instantaneous mode amplitude in terms of temperature fluctuation, \( Y_{\ell m}^m \) is the spherical harmonic associated with the mode with degree \( \ell \) and azimuthal order \( m \), and \( (r, \theta', \phi') \) (resp. \( (r, \theta, \phi) \)) the spherical coordinate system in the pulsation frame (resp. in the observer frame). As discussed in Appendix A, \( \left( \delta T/T \right) \) and hence \( \Theta_{\ell m}(t) \) are evaluated at the photosphere.

For a radial mode, the bolometric and intrinsic luminosity fluctuation is related to the relative intrinsic temperature fluctuation as:

\[
\left( \frac{\delta L}{L} \right)_{\ell=0}(t) = 4 \left( \frac{T_{\text{eff}}}{T_{\text{eff}}} \right)_0 = 4 \Theta_0(t)
\]

where \( T_{\text{eff}} \) is the effective temperature and \( L \) the luminosity of the star. Then, by extension of the radial case, we define, in the general case, the bolometric and intrinsic mode amplitude in terms of luminosity the quantity:

\[
\left( \frac{\delta L}{L} \right)_{\ell m}(t) \equiv 4 \Theta_{\ell m}(t)
\]

Note that, in the present case, since the mode excitation is a random process, we rather consider the rms quantities

\[
\left( \frac{\delta L}{L} \right)_{\ell m}^{\text{rms}} \equiv \sqrt{\left( \frac{\delta L}{L} \right)_{\ell m}^2(t)} = 4 \sqrt{\Theta_{\ell m}(t)}
\]

The rms label will however be generally omitted in the following for conciseness of the notations.

Then, we establish the relation between \( \left( \delta I/I \right)_{\ell m,i} \) (the observed relative intensity fluctuations due to a given mode \((\ell, m)\), for a given inclination \(i\)) and the intrinsic mode amplitude:

\[
\left( \frac{\delta I}{I} \right)_{\ell m,i} = R_{\ell m,i} \Theta_{\ell m} = \frac{R_{\ell m,i}}{4} \left( \frac{\delta L}{L} \right)_{\ell m}
\]

with \( R_{\ell m,i} \) is the instrumental response function associated with the mode with degree \( \ell \) and azimuthal order \( m \) and inclination \( i \). The expression for \( R_{\ell m,i} \) is:

\[
R_{\ell m,i} \equiv \int_0^1 d \lambda E(\lambda) \frac{d B_\lambda}{d \ln T} \frac{S_{\ell m,i}(\lambda)}{\int_0^1 d \lambda E(\lambda) B_\lambda}
\]

where \( S_{\ell m,i}(\lambda) \) is the so-called 'visibility' coefficient associated with the mode.

The visibility coefficient, \( S_{\ell m,i} \), measures the contribution of the mode integrated over the projected stellar surface, taking into account the effect of the limb-darkening (see e.g. Dziembowski [1977], Berthomieu & Provost [1990]). Expression for \( S_{\ell m,i} \) is given in Eq. (A.19). Note that in the case of radial modes, \( S_0 \) is independent of \( \lambda \) and \( S_0 = 1 \) by definition.

An interesting property of the visibility coefficients \( S_{\ell m,i} \) makes that, assuming equipartition of energy among different
modes of a same multiplet, the global visibility contribution of each multiplet (composed of modes of same radial order \( n \), same degree \( \ell \), and different azimuthal order \( m \)) is independent of the inclination \( i \) (Dziembowski 1977, Toutain & Gouttebroze 1993). It is thus possible to compute a global visibility function \( \Sigma_\ell = \sum_{m,i} S_{\ell,i} \) which is independent on \( i \) for the different multiplets. This property will be useful in the next section.

3.3. Response function for smoothed oscillation power density spectrum

In the case of stellar observations, as remarked by Kjeldsen et al. (2003) the measurement of individual modes or even individual multiplets might be delicate and it might give more precise results to estimate oscillation amplitudes from the smoothed oscillation power density contribution as represented in Sect.1. In this case, as suggested by Kjeldsen et al. (2005), the oscillation power density contribution \( (P_{\text{osc}}, \text{in} \, \text{ppm}^2/\mu\text{Hz}) \) is smoothed over typically three or four times the large separation (\( \Delta \)); then, once multiplied by the estimate of the large separation (in \( \mu\text{Hz} \)), it is representative of \( P_{\text{osc}} \ell \) the total power (in \text{ppm}^2) concentrated in all modes present in one large separation (of order \( n \)). Accordingly, we have

\[
P_{\text{osc}} \ell \simeq 2 P_{\text{osc}} \Delta
\]  

(12)

where \( \Delta \) is the large separation and the factor 2 multiplying \( P_{\text{osc}} \) is introduced to take into account the power density spread in the negative part of the spectrum. Let define \( P_{\text{osc},\ell,m} \) as the observed power (in \text{ppm}^2) associated with a mode \((\ell, m)\), with inclination \( i \). Assuming that \( \Theta_{\ell,m} \) is the same for all the modes that are within the same separation and using Eq. (7), it can easily shown that:

\[
P_{\text{osc}} \ell \equiv \sum_{m} P_{\text{osc},\ell,m} \Theta_{\ell,m}^2 \Theta_g^2(t) = \frac{P_{\text{osc}} L}{16} \left( \frac{\delta L}{L} \right)^2 \Theta_g^2(t) \]

(13)

with

\[
R_{\text{osc}} \equiv \sqrt{\sum_{\ell} R_{\ell}^2}
\]  

(14)

\[
R_{\ell} \equiv \int_{\lambda} d\lambda \frac{E(\lambda) dB_\lambda}{d\ln T} S_{\ell}(\lambda)
\]  

(15)

and \( \bar{\Theta}_g^2(t) \) is the mean square value of \( \Theta_g(t) \) for a radial mode. Note that in Eq. (13) the sum over \((\ell, m)\) is performed among all the multiplets within the same separation. The expression for the visibility coefficient \( S_{\ell} \) is given by Eq. (A.22). The visibility factor associated with modes \( \ell > 4 \) can be neglected. Accordingly, Eq. (14) can be simplified as:

\[
R_{\text{osc}} \equiv \sqrt{R_0^2 + R_1^2 + R_2^2 + R_3^2}
\]  

(16)

In practice, let consider \( P_{\text{osc}} \), the smoothed power density component associated with oscillations derived from observations, as in Sect.1. Using Eqs. (12), (13) and (9), one obtains the \textit{(rms)} bolometric amplitude normalised to radial mode given by

\[
A_{\text{bol,}\ell=0} \equiv \bar{\Theta}_g^2 \left( \frac{\delta L}{L} \right)^\text{rms} \equiv \frac{4}{R_{\text{osc}}} \sqrt{2 P_{\text{osc}} \Delta}
\]  

(17)

4. Results for different data sets

4.1. A reference solar bolometric oscillation amplitude

The resulting estimates of the bolometric amplitude per radial mode are shown in Fig.4 (\( R_{\text{osc}} \) values computed for the different data sets considered here are given in Tab. 3). We compare the curves obtained for each data set, with a special attention to the value at maximum often taken as a convenient characteristic measurement of the oscillations amplitudes in stars (see also Tab. 4). Although some residual of the initial difference seems to subsist (suggesting that our response function might be refined further), we notice a reasonable agreement of the different curves, within one-sigma error bar estimates. This allows us

| Resp. Func. | SPMa | SPMb | SPMc | PMOc |
|------------|------|------|------|------|
| \( R_{\text{osc}}(T_{\text{eff, Sun}}) \) | 11.63 | 9.02 | 5.26 | 7.15 |
| \( R_{\text{osc}}(T_{\text{eff, Sun}}) \) | 6.24 | 5.02 | 3.06 | 4.00 |

where \( R_{\text{osc}} \) is the response function given by Eq. (16) and computed for each data set using Eqs. (15) and (A.22).

In the present work, the \( S_{\ell}(\lambda) \) coefficients (Eq. (A.22)) are computed, taking into account monochromatic specific intensities derived from stellar atmosphere models (see Barban et al. 2003) with relevant \( T_{\text{eff}} \), [Fe/H], and \( \log g \).

3.4. Response function for granulation

As detailed in Appendix A, since we are interested in \textit{rms} values with time and assuming that these values are identical all over the stellar surface, the granulation component can be treated in a similar way than a radial mode. Accordingly, the relation between the observed relative intensity fluctuations and the associated intrinsic fluctuations is

\[
\left( \frac{\delta I}{I} \right)_{g}(t) = R_g \Theta_g(t) = \frac{R_g}{4} \left( \frac{\delta L}{L} \right)_{g}(t)
\]  

(18)

where the quantities have the same meaning than previously for radial modes but subscript \( g \) refers to the granulation and

\[
R_g = \int_{A} d\lambda E(\lambda) dB_{\lambda} = \int_{A} d\lambda E(\lambda) B_{\lambda}
\]  

(19)

As for the radial modes, we define the \textit{rms} and intrinsic relative luminosity fluctuation due to granulation the quantity

\[
\left( \frac{\delta L}{L} \right)_{g}^{\text{rms}} \equiv \sqrt{\left( \frac{\delta L}{L} \right)_{g}^2(t)} = 4 \sqrt{\Theta_g^2(t)} = \frac{4}{R_g} \left( \frac{\delta L}{L} \right)_{g}^{\text{rms}}(t)
\]  

(20)

If we consider the power density contribution associated with granulation \( (P_g) \) determined in Sect.1, we can derive the corresponding bolometric power density spectrum according to

\[
P_{\text{g,bol}} \equiv 16 P_g/R_g^2
\]  

(21)

which is expected to characterize granulation independently of the instrument considered. The application to the different data sets obtained on the Sun \( (R_g \text{ values are given in Tab. 3) with different instrumental techniques and with different band passes reveal a good agreement (see Sect. 4).}

4. Results for different data sets
to propose as reference for the Sun a $2.53 \pm 0.11 \mu$ppm of maximum bolometric amplitude per radial mode (mean of the four values ponderated by $1/\sigma_i$). We checked that this result was not affected significantly by changing the smoothing boxcar width from 2 times to 4 times $\Delta$.

4.2. A reference bolometric granulation power density spectrum

The different mean profiles of bolometric background power density spectra are shown in Fig. 5. Here again, we notice the good agreement of the different curves. Coefficients characterizing the different curves are given in Table 4 as well as reference values proposed for the Sun background contribution. Here again, the influence of the size of the smoothing boxcar (between 0.1 to 4 times $\Delta$) has been tested and found negligible within the present error bars.

Table 4. Bolometric parameters. The last line corresponds to reference values resulting from a mean of the values given in the other lines, ponderated by $1/\sigma_i$.

5. Response functions of CoRoT for objects on the Main Sequence

Stellar atmosphere models are computed with the Atlas 9 code [Kurucz 1993 in a modified version including the CGM convection (Heiter et al. 2002, see). Considering the CoRoT total efficiency shown in Fig. 6 we compute the CoRoT response functions for stellar atmosphere models characterized by different values of $T_{eff}$, $\log g$ and chemical compositions illustrating possible solar-like candidates on the Main Sequence $(1 < [Fe/H] < 1, 3.9 < \log g < 4.5, 5800 < T_{eff} < 6750 K)$. As shown in Fig. 7, the dependency of the CoRoT response function $R_{osc}$ to $\log g$ and chemical composition is small in the considered range. To a great extent (within 0.6%), it can be neglected and $R_{osc}$ as $R_g$ can be described as simple polynomial functions of $T_{eff}$ only:

$$R_{osc}(T_{eff}) = R_{osc}(T_{eff, Sun}) + A(T_{eff} - T_{eff, Sun}) + B(T_{eff} - T_{eff, Sun})^2.$$  

We proceed the same way for $R_g$. 

Fig. 6. CoRoT total efficiency.
values obtained for the fit are given in Tab. 5.

6. Conclusions

Measurement of stellar oscillations or granulation brings instrumental values which depend on the instrumental technique and bandpass and on the star considered. In this work, with the purpose of helping future comparisons between stars observed in photometry,

1. we propose a simple expression for response functions connecting specific instrumental photometric measurements with intrinsic bolometric values for oscillation amplitudes and granulation power density.
2. we test and validate this expression on four sets of data obtained on the Sun, in four different bandpasses and with two different instrumental techniques.
3. we establish reference bolometric measurements for the solar oscillation amplitudes ($2 \times 10^{-6}$) and for the solar granulation power density.
4. we compute the response functions for the CoRoT instrument and give an analytic expression for it.

Acknowledgements. SOHO is a mission of international collaboration between ESA and NASA.

Appendix A: Derivation of the instrumental response functions

We derive here the relation between the observed flux fluctuation and the intrinsic temperature fluctuations induced by the presence of non-radial modes or granulation on the surface of the star. We proceed in the manner of Berthomieu & Provost (1990). We summarize the main steps and emphasize the approximations that we adopt in the present study. The flux, $F_\lambda$, received from the star at the wavelength $\lambda$ is given by (see Berthomieu & Provost 1990):

$$F_\lambda = \int d\mathcal{A} I_\lambda(\tau = 0, \mu)$$

where $\mathcal{A}$ is the total observed surface, $d\mathcal{A} = dA \cdot n$ the elementary observed surface around the direction of the observer, $n$ a unit vector in the direction of the observer, $dA$ the differential surface element perpendicular to the stellar surface, $\tau$ the optical depth, $\mu = \cos(\theta)$, and $I_\lambda(\mu)$ the specific intensity at the wavelength $\lambda$. We adopt a spherical coordinate system with the $z$-axis pointing toward the observer. The specific intensity is assumed to be invariant with respect to any rotation along the $z$-axis, this is why here $I_\lambda$ depends only on $\mu$. Note that the integral of Eq. (A.1) is evaluated at the optical depth $\tau = 0$.

We define the limb-darkening function, $g_\lambda$, as

$$g_\lambda(\mu) \equiv \frac{I_{\lambda}(\mu)}{I_{\lambda}(1)}$$

where $I_{\lambda}(1) = I_{\lambda}(\mu = 1)$. Finally, we define the mean intensity as the quantity

$$J_\lambda \equiv \frac{1}{4\pi} \int d\Omega I_\lambda(\mu)$$

where $d\Omega$ is the elementary solid angle. Using Eqs. (A.2) and (A.3), we then derive the relation:

$$J_\lambda = I_\lambda(1)/H_\lambda$$

where we have defined

$$H_\lambda = 2 \left( \int_0^1 d\mu g_\lambda(\mu) \right)^{-1}$$

According to Eqs. (A.1), (A.2) and (A.4), a small variation of $F_\lambda$ is given by

$$\delta F_\lambda = \int_\mathcal{A} d\mathcal{A} \left( \bar{g}_\lambda \delta J_\lambda + J_\lambda \delta \bar{g}_\lambda + J_\lambda \bar{g}_\lambda \delta H_\lambda \right)$$

$$+ \delta (d\mathcal{A}) \bar{J}_\lambda \bar{g}_\lambda$$

where $\bar{g}_\lambda$ refers to equilibrium quantity. The first term in RHS of Eq. (A.6) corresponds to the perturbations of the mean intensity evaluated at an effective optical depth $\tau = \tau_0$ in the atmosphere. This effective optical depth corresponds to the layer that contribute predominantly to the variation of the emergent flux (see Berthomieu & Provost 1990). As in Berthomieu & Provost (1990), we assume that $\bar{g}_\lambda$ and hence $H_\lambda$ do not depend on $\tau_0$ and are evaluated at $\tau = 0$.

The three last terms in RHS of Eq. (A.6) are the perturbation of the limb-darkening function and the surface distortion (for details see Berthomieu & Provost 1990). All these perturbations are shown to have a negligible contribution to $\delta F_\lambda$ compared to that of $\delta J_\lambda$. Accordingly, Eq. (A.6) can be simplified as:

$$\delta F_\lambda = \int_0^{2\pi} d\phi \int_0^1 d\mu \mu g_\lambda(\mu) H_\lambda \delta J_\lambda ,$$

where we have dropped $\bar{\lambda}$ from $g_\lambda$ and $H_\lambda$.

We place ourself in Local Thermodynamic Equilibrium and assume adiabatic perturbations for linearisation, accordingly $\delta J_\lambda = \delta B_\lambda$ where $B_\lambda$ is the black body law which expression is

$$B_\lambda = \frac{2hc^2}{\lambda^5} \frac{1}{e^{hc/\lambda kT} - 1}$$

where $T$ is the local temperature, $c$ the speed of the light, $h$ Planck’s constant, and $k$ Boltzmann’s constant.

The local variation of $B_\lambda$ is induced by a local variation of $T$. Assuming small perturbations, we have

$$\delta J_\lambda = \delta B_\lambda = \left( \frac{dB_\lambda}{d\ln T} \right) \frac{\delta T}{T} \left( \tau_0, t, \theta, \phi \right)$$

Using Eqs. (A.9) and (A.15), Eq. (A.7) can then be written as:

$$\delta F_\lambda = H_\lambda \left( \frac{dB_\lambda}{d\ln T} \right) \int_0^{2\pi} d\phi \int_0^1 d\mu \mu g_\lambda(\mu) \frac{\delta T}{T}$$

Finally, we approximate Eq. (A.1) as

$$F_\lambda = 2\pi H_\lambda G_\lambda B_\lambda$$

where $B_\lambda$ is evaluated at the photosphere, i.e. at $T = T_{\text{eff}}$ and where we have defined

$$G_\lambda \equiv \int_0^1 d\mu \mu g_\lambda(\mu).$$

The relative variation of the total flux $I$ received by the instrument is finally given by

$$\left( \frac{\delta I}{I} \right) = \int_0^{2\pi} d\phi \int_0^1 d\mu \mu g_\lambda(\mu) \frac{\delta T}{T}$$

where $E(\lambda)$ is the global efficiency in terms of energy of the instrument at a given wavelength. The function $E(\lambda)$ is normalised as

$$\int_0^{2\pi} d\phi \int_0^1 d\mu \mu g_\lambda(\mu) \frac{\delta T}{T} = 1$$

### A.1. Non radial oscillations

In the case of a non-radial spheroidal mode, $\delta T/T$ is by definition:

$$\left( \frac{\delta T}{T} \right) \left( \tau_0, t, \theta, \phi \right) = \Theta_t(t, \tau_0) Y_{\ell m}^\prime(\theta', \phi')$$

where $\Theta_t(t, \tau_0)$ is the intrinsic and instantaneous mode amplitude in terms of temperature fluctuation, $Y_{\ell m}^\prime$ is the spherical harmonic associated with the mode with a degree $\ell$ and azimuthal order $m$, and $(\ell, \ell', \ell'')$ the spherical coordinate system in the pulsation frame. The pulsation frame is choosen such that its polar axis coincides with the star rotation axis. The spherical harmonic, $Y_{\ell m}^\prime$, is here normalized as:

$$\int d\Omega' \left| Y_{\ell m}^\prime(\theta', \phi') \right|^2 = 4\pi$$

where $\Omega'$ is the elementary solid angle associated with the pulsation coordinate system. Note that for low $\ell$ degree, $\Theta_t(t, \tau_0)$ is expected to negligibly depend on $\ell$ (Belkacem et al. 2008).

As shown by Berthomieu & Provost (1990), for low $\ell$ degree, $\tau_0$ marginally depends on $\ell$. Furthermore, they show that – in the Sun – the optical depth $\tau_0$ is very close the the photosphere, which by definition corresponds to the layer $T = T_{\text{eff}}$ and $\tau = 2/3$. Then, from here, we will assume that $\tau_0$ coincides with the photosphere ($\tau = 2/3$).

Using Eqs. (A.10), (A.11), (A.13), (A.12), and (A.15), we then derive the flux variation due to the mode:

$$\left( \frac{\delta I}{I} \right) = R_{\ell m,i} \Theta_t(t)$$

with

$$R_{\ell m,i} \equiv \int_0^{2\pi} d\phi \int_0^1 d\mu \mu g_\lambda(\mu) \frac{\delta T}{T}$$

where we have defined the ‘visibility’ coefficient, $S_{\ell m,i}$, as the quantity:

$$S_{\ell m,i}(\lambda) \equiv \int_0^{2\pi} d\phi \int_0^1 d\mu \mu g_\lambda(\mu) \frac{\delta T}{T}$$

Note that, by definition of $S_{\ell m,i}$, we have for $S_{01}$ a radial mode.

By using stellar atmosphere models, we find that – in the domain of $T_{\text{eff}}$ and gravity we are interested here – $G_\lambda H_\lambda$ varies
slowly with \( \lambda \) compared to \( B_\lambda \) and \( dB_\lambda / d \ln T \). Accordingly, Eq. (A.18) can be simplified as:

\[
R_{\ell,m,i} \equiv \int_\lambda^\Delta \frac{d \mu E(\lambda)}{d \ln T} \frac{dB_\lambda}{d \ln T} S_{\ell,m,i}(\lambda) \int_\lambda^\Delta d \lambda E(\lambda) B_\lambda
\]

(A.20)

Following Dziembowski (1977), we can decompose \( S_{\ell,m,i}(\lambda) \) as:

\[
S_{\ell,m,i} = q_{\ell,m,i}(\lambda) S_\ell(\lambda)
\]

(A.21)

where \( i \) is the angle between the observer and the rotation axis and \( P_\ell^m(\mu) \) the associated Legendre function.

The bolometric flux variation, \( (\delta I/I)_\text{bol} \), is obtained from Eq. (A.17) by assuming in Eq. (A.20) a constant \( E(\lambda) \), this gives

\[
\left( \frac{\delta I}{I} \right)_\text{bol} (t) = R_{\ell,m,i}^{\text{bol}} \Theta_\ell(t)
\]

(A.24)

with

\[
R_{\ell,m,i}^{\text{bol}} \equiv \frac{\pi}{\sigma T^4_{\text{eff}}} \int d \lambda \frac{dB_\lambda}{d \ln T} S_{\ell,m,i}(\lambda)
\]

(A.25)

For a radial mode, \( S_{0,0} = 1 \) and \( R_{\ell,m,i}^{\text{bol}} = 4 \). We have then for a radial mode:

\[
\left( \frac{\delta I}{I} \right)_\text{bol} (t) = 4 \Theta_\ell(t)
\]

(A.26)

By definition of the effective temperature (\( T_{\text{eff}} \)) and the stellar radius \( R_* \), the total luminosity of the star, \( L \), is given by the Stefan’s law:

\[
L = 4\pi \sigma T^4_{\text{eff}} R^2_*
\]

(A.27)

where \( \sigma \) is Stefan’s constant. Variation of the stellar radius due to the mode can be neglected. Accordingly, the relative variation of \( L \) due to a radial mode is given by the relation

\[
\left( \frac{\delta L}{L} \right) = 4 \left( \frac{\delta T_{\text{eff}}}{T_{\text{eff}}} \right)
\]

(A.28)

Beside, we have again for a radial mode:

\[
\left( \frac{\delta I}{I} \right)_\text{bol} (t) = \left( \frac{\delta L}{L} \right)
\]

(A.29)

Then, according to Eqs. (A.26) and (A.28), we have

\[
\left( \frac{\delta T_{\text{eff}}}{T_{\text{eff}}} \right) = \Theta_0
\]

(A.30)

As a conclusion, for a radial mode, \( \Theta_0 \) (resp. \( (\delta I/I)_\text{bol} \)) is then directly related to a variation of \( T_{\text{eff}} \) (resp. \( L \)). On the other hand, for a non-radial mode, \( (\delta I/I)_\text{bol} \) is related to the intrinsic mode amplitude in terms of temperature, \( \Theta_\ell \), through the coefficient given by Eq. (A.25) that depends on the mode geometry and the limb-darkening law. However, by extension of the radial case, we define, in the general case, the bolometric and intrinsic mode amplitude in terms of luminosity the quantity:

\[
\left( \frac{\delta L}{L} \right)_\ell \equiv 4 \Theta_\ell
\]

(A.31)

Now, according to Eqs. (A.17) and (A.31), we can write:

\[
(\delta I/I)_\ell(t) = R_{\ell,m,i} \Theta_\ell = \frac{R_{\ell,m,i}}{4} \left( \frac{\delta L}{L} \right)_\ell
\]

(A.32)

The Eq. (A.32) then relates the observed intensity fluctuations to the bolometric and intrinsic mode amplitude in terms of luminosity.

### A.2. Granulation

We define \( (\delta T/T)_g = \Theta_g(\ell, \mu, \phi) \) as the relative temperature perturbations due to the granulation at the instant \( t \) and the position \((\theta, \phi)\).

As for the mode, we derive the flux perturbation, \( \delta I_{\ell, t} \), due to the granulation:

\[
(\delta I/I)_g(t) = \int d \lambda E(\lambda) \delta F_{\ell, t}
\]

(A.33)

with

\[
\delta F_{\ell, t} = \int d \lambda E(\lambda) \frac{d B_\lambda}{d \ln T} \int_0^{2\pi} d \phi \int_0^1 d \mu \mu g_\lambda(\mu) \Theta_g(\ell, \mu, \phi)
\]

(A.34)

To go further, one needs to know how temperature fluctuations due to the granules are distributed along the star surface. We note that we are only interested in the time averaged intensity fluctuations. As a simplification, we assume that distribution of the temperature fluctuations is – in time average – homogeneous. Accordingly, we can ignore the dependence of \( \Theta_g \) with \((\mu, \phi)\). This is formally equivalent to assume in Eq. (A.15) that \( Y^m_\ell = 1 \), as for a radial mode \((\ell, m) = (0,0))\). Then, the expression for \( (\delta I/I)_g \) is derived from Eqs. (A.32) and (A.20) by assuming \((\ell, m) = (0,0))\). Accordingly, \( (\delta I/I)_g \) can be written as

\[
(\delta I/I)_g(t) = R_g \Theta_g(t) = \frac{R_g}{4} \left( \frac{\delta L}{L} \right)_g(t)
\]

(A.35)

with

\[
R_g = R_{\ell=0, m=0} \equiv \int d \lambda E(\lambda) \frac{d B_\lambda}{d \ln T} \int_\lambda^\Delta d \lambda E(\lambda) B_\lambda
\]

(A.36)

\[
\left( \frac{\delta L}{L} \right)_g = 4 \Theta_g
\]

(A.37)

As for the radial modes, \( \left( \frac{\delta L}{L} \right)_g \) represents the bolometric and intrinsic luminosity variation due to the granulation.
