ABSTRACT:

This study aimed to evaluate the effects of increasing levels of β-glucanase on modulation of jejunal mucosa-associated microbiota in relation to nutrient digestibility and intestinal health of pigs fed diets with 30% corn DDGS and xylanase. Forty pigs at 12.4 ± 0.5 kg BW were allotted in a RCBD with initial BW and sex as blocks. Dietary treatments consisted of a basal diet with xylanase (1,500 EPU/kg) and increasing levels of β-glucanase (0, 200, 400, and 600 U/kg) meeting nutrient requirements and fed to pigs for 21 d. Blood samples were collected at d 19. At d 21, all pigs were euthanized to collect intestinal tissues and digesta. Tumor necrosis factor alpha (TNFα), IL-6, and MDA were measured in plasma and mid-jejunal mucosa. Viscosity was determined using digesta from the distal jejunum. Ileal and rectal digesta were evaluated to determine AID and ATTD of nutrients. Mucosa samples from the mid-jejunum were utilized for microbiota sequencing. Data were analyzed using the MIXED procedure on SAS 9.4. Overall, increasing dietary β-glucanase tended to increase (Linear; \( P = 0.077 \)) the ADG of pigs. Increasing dietary β-glucanase affected (quadratic; \( P < 0.05 \)) the relative abundance of Bacteroidetes, reduced (linear; \( P < 0.05 \)) Helicobacter rappini, whereas increased (Linear, \( P < 0.05 \)) Faecalibacterium prausnitzii. β-glucanase supplementation (0 vs. others) tended to increase (\( P = 0.096 \)) the AID of CP in the diet, whereas increasing dietary β-glucanase tended to increase (Linear; \( P = 0.097 \)) the ATTD of GE in the diet and increased (Linear; \( P < 0.05 \)) the concentration of IL-6 in the plasma of pigs. In conclusion, increasing β-glucanase up to 600 U/kg feed in a diet containing xylanase (1,500 EPU/kg) modulated mucosa-associated microbiota by increasing the relative abundance of beneficial bacteria and reducing potentially harmful bacteria. Furthermore, increasing β-glucanase up to
600 U/kg feed in a diet containing xylanase (1,500 EPU/kg feed) enhanced the status of intestinal environment and nutrient utilization, as well as reduced systemic inflammation of pigs, collectively resulting in moderate improvement of growth performance. Supplementing β-glucanase at a range of 312 to 410 U/kg with xylanase at 1,500 EPU/kg feed showed the most benefit on jejunal mucosa-associated microbiota and reduced systemic inflammation of pigs.

Keywords: β-glucanase, growth performance, intestinal health, microbiota, nursery pigs, xylanase
List of Abbreviations: ADFI, average daily feed intake; ADG, average daily gain; AID, apparent ileal digestibility; ANF, anti-nutritional factor(s); ATTD, apparent total tract digestibility; BCA, bicinchoninic acid; BW, body weight; CP, crude protein; DDGS, distiller's dried grains with solubles; DM, dry matter; EPU, endo-pentosanase units; FTU, phytase unit; GE, gross energy; G:F, gain to feed ratio; GIT, gastrointestinal tract; IL-6, interleukin 6; LPS, lipopolysaccharides; MDA, malondialdehyde; NSP, non-starch polysaccharide(s); OTU, operational taxonomic unit; PBS, phosphate-buffered saline; RCBD, randomized complete block design; SID, standardized ileal digestible; STTD, standardized total tract digestible; TBARS, thiobarbituric acid reactive substance; TLR3, Toll-like receptors 3; TLR4, Toll-like receptors 4; TNFα, tumor necrosis factor alpha; VH:CD ratio, villus height to crypt depth ratio; XOS, xylooligossaccharide(s).
INTRODUCTION

Typical feeds for pigs are mainly composed of plant-based feedstuffs. Non-starch polysaccharides (NSP) present in plant-based feedstuffs are considered anti-nutritional factors (ANF) due to their associated physicochemical properties. A typical corn and soybean meal-based diet contains about 2.3 to 3.8% of arabinoxylans (Knudsen, 1997; Jaworski et al., 2015) and 0.6 to 2.1% of β-glucans (Mathlouthi et al., 2002a; Sampson et al., 2015; Yu et al., 2018), whereas NSP concentrations are influenced by feedstuffs used in feeds. Use of co-products such as DDGS in feeds further increases NSP concentrations (Pedersen et al., 2014; Jaworski et al., 2015).

Major anti-nutritional roles of xylans and β-glucans are related to their capacity to increase digesta viscosity causing encapsulation of nutrients, and thus reducing nutrient digestibility in feeds. In addition, increased digesta viscosity cause reduced passage rate and thus increased amounts of undigested nutrients provide luminal environment for the proliferation of harmful microbiota (McDonald et al., 2001; Wellock et al. 2008; Metzler-Zebeli et al., 2010; Agyekum and Nyachoti, 2017) resulting in intestinal immune response, oxidative stress, and eventually reduced growth performance (Chen et al., 2020; Duarte et al., 2020; Kim and Duarte, 2021). These effects can be even more pronounced in nursery pigs due to their inability to adapt to dietary challenges as well as their limited capability of handling NSP (Lindberg, 2014; Niu et al., 2015).

In pig production, xylanase has been largely adopted to handle anti-nutritional effects of xylans and the use of β-glucanase is increasing to handle β-glucans from grains (Adeola and Cowieson, 2011). The main mode of action is by reducing digesta viscosity which will in turn can modulate the intestinal microbiota (Owusu-Asiedu et al., 2006; Zhang et al., 2018; Petry et al., 2020), increase nutrient digestibility and enhance the intestinal health and finally improve growth performance of pigs (Ji et al., 2008; Passos et al., 2015; Chen et al., 2020).
Most studies have evaluated supplemental effects of xylanase or β-glucanase individually (Li et al., 1996; Passos et al., 2015), whereas these enzymes are often supplemented together in pig production considering the complexity and the variety of NSP in plant-based feeds (Mathlouthi et al., 2002b; Tsai et al., 2017).

A recent study (Chen et al., 2020) evaluated the effects of increasing levels of xylanase on intestinal health and growth performance of nursery pigs. Chen et al. (2020) demonstrated that xylanase effectively enhanced intestinal health and growth performance of nursery pigs which were obtained at 1,500 EPU xylanase/kg. Based on Chen et al. (2020), this study further evaluated the effects of increasing levels of β-glucanase in feeds containing 1,500 EPU xylanase/kg. Therefore, it was hypothesized that β-glucanase would hydrolyze β-glucan reducing digesta viscosity, increasing the digestibility of nutrients, increasing proliferation of health benefiting microbiota in the jejunal mucosa, and thus enhancing the intestinal health and growth of nursery pigs fed diets with xylanase. Thus, this study aimed to evaluate the effects of increasing levels of β-glucanase on modulation of jejunal mucosa-associated microbiota in relation to nutrient digestibility and intestinal health of pigs fed corn soybean meal-based diets supplemented with 30% corn DDGS and xylanase.

MATERIALS AND METHODS

The experimental procedures used in this study were reviewed and approved by the Institutional Animal Care and Use Committee at North Carolina State University.

Animals, Experimental Design, and Diets

Forty nursery pigs (20 barrows and 20 gilts) at 6 wk of age (21 d post-weaning) and 12.4 ± 0.5 kg BW were allotted to 4 dietary treatments (n = 10) based on a randomized complete block design with sex and initial BW serving as the blocks. A basal diet (Table 1) was formulated to meet the nutritional requirements suggested by NRC (2012). The experimental diets were supplemented with increasing levels of β-glucanase (0, 200, 400, and
600 U β-glucanase/kg feed) and xylanase (1,500 EPU/kg feed; Hostazym X 100, Huvepharma, Peachtree City, GA). The enzymes were premixed for each treatment to have an equal inclusion level of 0.01% for all treatments. Before the study, from weaning to d 21 post-weaning, all pigs were fed a common corn soybean meal-based diet formulated to meet the nutritional requirements suggested by NRC (2012).

The analyzed enzyme activity in the tested mixtures is described in Table 1. One endo-pentosanase unit (EPU) is the amount of enzyme needed for the release of 8.3 nmol of reducing sugars (xylose equivalent) per minute from oat spelt xylan at pH 4.7 and 50°C. One unity of endo-1,4-β-glucanase (U) activity is defined as the amount of enzyme needed for the release of 0.128 micromoles of reducing sugars (glucose equivalents) per minute from barley β-glucan at pH 4.5 and 30°C.

Pigs were individually housed in pens and fed the assigned experimental diets for 21 d. Body weight and feed intake were measured weekly to analyze the ADG, ADFI, and G:F ratio as indicators of growth performance. On d 16 of the study, titanium dioxide (0.4%) was added to the feed as an indigestible marker to calculate the digestibility upon collection of digesta at d 21 of experiment.

Samples Collection, and Processing

Blood samples were collected at d 19 of the study into vacutainer tubes containing EDTA, placed on ice and centrifuged (3,000 × g at 4°C for 15 min) to obtain plasma. Samples were aliquoted and stored at -80°C for further analysis of tumor necrosis factor alpha (TNF-α), interleukin-6 (IL-6), and malondialdehyde (MDA) as indicators of systemic inflammatory status.

At the end of the study (d 21), all pigs were euthanized to collect intestinal tissues and digesta. Tissues from the mid-jejunum (3 m after the pyloric duodenal junction) and mid-colon were collected and washed with a sterile saline solution (0.9%). Each intestinal
segment was longitudinally opened and gently scraped to obtain mucosa layers. The mucosa samples were collected into 2 mL vials, snap frozen in liquid nitrogen and then transferred to a -80°C freezer. Intestinal mucosa samples collected from each segment (500 mg) were suspended in 1 mL of phosphate-buffered saline (PBS) and homogenized on ice with a tissue grinder (Tissuemiser; Thermo Fisher Scientific Inc. Waltham, MA). The homogenized mucosa samples were centrifuged at 14,000 × g at 4°C for 3 min and the supernatant was aliquoted into 0.5 mL vials and stored at -80°C for further analysis of total protein, TNFα, IL-6, and MDA. Section of jejunum of each pig was fixed in 10% buffered formalin and further used for immunohistochemistry with Ki-67 staining and histomorphology measurement.

Digesta from the distal jejunum was collected into 50 mL tubes and placed on ice to measure viscosity immediately following collection. Digesta collected from the ileum and rectum (50 mL) were weighed, placed on ice, and then stored at -20°C. In order to collect the sufficient volume of ileal digesta (50 mL) pigs were fasted for 6 h and refed for 6 h before euthanasia. The sample collection of all pigs was concluded within 2 h. The samples from the ileum and rectum were then freeze dried, weighed, and finely ground for chemical analysis to calculate digestibility of dry matter (DM), ether extract (EE), gross energy (GE), and crude protein (CP, 6.25 × N).

Viscosity

Digesta collected from the distal jejunum were divided into 2 tubes (15 mL) and centrifuged at 1,000 × g at 4°C for 10 min. The supernatant of each tube was collected into 2 mL tubes and centrifuged at 10,000 × g at 4°C for 10 min. The supernatant was then transferred to a new 2 mL tube and kept on ice for measurement of viscosity. A viscometer (Brookfield Digital Viscometer, Model DV-II Version 2.0, Brookfield Engineering Laboratories Inc., Stoughton, MA) was then used to measure the digesta viscosity at 25°C.
The viscosity was calculated as the average between 45.0/s and 22.5/s shear rates and recorded as millipascal-seconds (mPa.s) (Duarte et al., 2019; Chen et al., 2020).

**Microbiome Sequencing**

Mucosa samples collected from the mid-jejunum were used for mucosa-associated microbiome sequencing using the 16S rRNA gene sequence analysis. The DNA was extracted using the DNA Stool Mini Kit (#51604, Qiagen; Germantown, MD) following the instructions of the manufacturer. The extracted DNA samples were sent to the Genomics Department of Mako Medical Laboratories (Raleigh, NC) for 16S rRNA gene sequencing as reported by Jang et al. (2021). Briefly, extracted DNA samples were prepared for template on the Ion Chef™ instrument and sequencing on the Ion S5™ system (Thermo Fisher Scientific Inc). Variable regions V2, V3, V4, V6, V7, V8, and V9 of the 16S rRNA gene were amplified using Ion 16S Metagenomics Kit (Thermo Fisher Scientific Inc.). Sequences (Hypervariable regions) were processed via Torrent Suite™ Software (version 5.2.2) (Thermo Fisher Scientific Inc.) to produce .bam files for further analysis. The taxonomy was assigned against the GreenGenes (anybody) and MicroSeq (experts) databases, specific primers for microbiota. Alpha and beta diversity rare fraction plot generation, and the Operational Taxonomic Unit (OTU) table generation were performed by the Ion Reporter™ Software Suite (version 5.2.2) of bioinformatics analysis tools (Thermo Fisher Scientific Inc.) with 98% similarity. The Ion Reporter’s Metagenomics 16S workflow powered by Qiime (version w1.1) was used to analyze the samples. The depth of sequencing coverage was > 1,000 × sample preparation. To initiate the statistical analysis of the microbiota, OTU data were transformed to relative abundance. The OTU with the relative abundance < 0.5% within each level were combined as “Others”.
Measurement of Immune and Oxidative Stress Status

Total protein, TNF-α, IL-6, and MDA concentrations were measured using colorimetric methods. A plate reader (Synergy HT, BioTek Instruments, Winooski, VT) and the software (Gen5 Data Analysis Software, BioTek Instruments) were used to measure the absorbance. The standard curves generated from the concentration and absorbance of the standard from each kit were used to calculate the respective concentration.

Total protein concentration in the mucosa of the mid-jejunum and mid-colon was determined using a Bicinchoninic Acid (BCA) Protein Assay (23225#, Thermo Fisher Scientific Inc.) as described by Chen et al. (2020). Prior to the assay, mucosa samples were tested to determine the dilution factor. Samples obtained from the mid-jejunum and mid-colon were diluted at (1:40) in PBS to enable the working range of the assay to be between 20 and 2,000 μg/mL. The wavelength to measure the absorbance was set at 562 nm. The total protein concentration was used to normalize the concentrations of TNF-α, IL-6, and MDA in the mucosa of mid-jejunum and mid-colon.

The concentration of TNF-α was measured in the plasma and mucosa of both the mid-jejunum and mid-colon using the Porcine TNF-α Quantikine ELISA Kit (PTA00; R&D System Inc. Minneapolis, MN) with a working range of 23.4 to 1,500 pg/mL as described by (Jang et al., 2020). The concentration of IL-6 in the mucosa of jejunum was determined using the Porcine IL-6 Quantikine ELISA Kit (P6000B; R&D System Inc.) with a working range of 18.8 to 1,200 pg/mL as described by Duarte et al. (2020). Absorbance was measured at 450 nm and 540 nm and the concentration of TNF-α, and IL-6 was reported as pg/mL and pg/mg protein, respectively in plasma and mucosa.

The concentration of MDA in plasma and mucosa of the mid-jejunum and mid-colon were measured using the Thiobarbituric Acid Reactive Substance (TBARS) Assay Kit (STA-330, Cell Biolabs, San Diego, CA) with a working range at 0.98 to 125 μmol/L. The
absorbance was measured at 532 nm and the concentration of MDA in plasma and mucosa was reported as μmol/mL and μmol/mg protein, respectively (Zhao and Kim, 2020).

**Intestinal histomorphology and Immunohistochemistry**

Two sections of mid-jejunum per pig were cut placed in cassettes and sent to the North Carolina State University Histology Laboratory (College of Veterinary Medicine, Raleigh, NC) for staining using Ki-67 immunohistochemistry assay as previous reported by Holanda et al. (2020). Pictures of 10 well-oriented villi and were taken at magnification 40× using a microscope Olympus CX31 (Lumenera Corporation, Ottawa, Canada) with a camera Infinity 2-2 digital CCD to measure the villus height, villus width, and crypt depth and then calculate the villus height to crypt depth (VH:CD) ratio following (Kim et al., 2019). Images of 10 intact crypts from each slide, taken at magnification 100× were cropped and used for determine the enterocyte proliferation rate by analyzing the percentage of Ki-67 positive cells using the ImageJS software (Jang and Kim, 2019). All analyses of the intestinal histomorphology were executed by the same person. The averages of the 10 measurements per pig were used one unit for statistical analysis.

**Digestibility**

Samples of diets and freeze dried digesta from the ileum and rectum were analyzed to determine DM (Method 934.01, AOAC, 2006), EE (Method 2003.06, AOAC, 2006), GE using a calorimeter (6200, Parr Instrument Company, Moline, IL), CP was determined using a TruSpec N Nitrogen Determinator (LECO Corp., St. Joseph, MI), and titanium dioxide following Myers et al. (2004). The digestibility of DM, GE, EE, and CP was calculated using the equation previously described by Duarte et al. (2019):

\[
\text{Digestibility} = \left\{ 1 - \left[ \frac{\text{TiO}_2\text{diet}}{\text{TiO}_2\text{digesta}} \times \left( \frac{\text{Nutrient}_{\text{digesta}}}{\text{Nutrient}_{\text{diet}}} \right) \right] \right\} \times 100;
\]

With TiO\text{2diet} and TiO\text{2digesta} denoting the concentrations of titanium dioxide in the diet and in the digesta from either the ileum or rectal; Nutrient\text{digesta} and Nutrient\text{diet} indicating the
concentrations of nutrients in the digesta from the ileum or rectum as well as in the diet. The digestibility of nutrients was reported as apparent ileal digestibility (AID) and apparent total tract digestibility (ATTD).

Statistical Analyses

Data were analyzed using the MIXED procedure in SAS 9.4 (SAS Inc., Cary, NC). Dietary treatments were considered fixed effects. Initial BW blocks and sex were considered the random effect. The linear and quadratic effects of increasing levels of β-glucanase were tested by polynomial contrasts \( N = 40 \). A preplanned contrast was performed using the CONTRAST statement to evaluate the effects of β-glucanase supplementation (0 vs. others). The coefficients for orthogonal polynomials were generated using the procedure IML. When a quadratic effect was found, the procedure RSREG was used to predict the critical value and the stationary point. The procedure CORR was used to generate the correlation among variables. Statistical differences were considered significant at \( P < 0.05 \). Tendency was considered at \( 0.05 \leq P < 0.10 \).

RESULTS

Growth Performance

Increasing levels of β-glucanase did not affect ADG of pigs until d 14 of experiment (Table 2) whereas, it tended to increase ADG (Linear; \( P = 0.068 \)) of pigs during d 14 to 21 of experiment. Overall, increasing levels of β-glucanase tended to increase (Linear; \( P = 0.077 \)) ADG of pigs without affecting ADFI or G:F during 21 d period.

Jejunal Mucosa-Associated Microbiota

The average of sequence reads per sample was 14,084 ± 2,110. At the phylum level (Table 3), increasing levels of β-glucanase in the diet of nursery pigs did not affect the relative abundance of Proteobacteria, Firmicutes, Tenericutes, Spirochaetes, and Others (Combined phyla with relative abundance lower than 0.05%). Increasing levels of β-
glucanase however tended to increase (Linear; \( P = 0.076 \)) and affect (Quadratic; \( P < 0.05 \)) the relative abundance of Bacteroidetes (maximum 22.29\% at 408 U/kg feed) in jejunal mucosa of nursery pigs. The Firmicutes to Bacteroidetes ratio (F:B) tended to be affected (Quadratic; \( P = 0.076 \)) by increasing levels of β-glucanase in the diet.

At the family level (Table 4), increasing levels of β-glucanase in the diet of nursery pigs affected (Quadratic; \( P < 0.05 \)) the relative abundance of Prevotellaceae (maximum 18.77\% at 405 U/kg feed). Dietary inclusion of β-glucanase (0 vs. others) reduced the relative abundance of Campylobacteraceae (\( P < 0.05 \)) whereas increasing levels of β-glucanase supplementation tended to reduce the relative abundance (Linear; \( P = 0.084 \)). Conversely, increasing levels of β-glucanase in the diet of nursery pigs increased (Linear; \( P < 0.05 \)) the relative abundance of Lachnospiraceae, and Ruminococcaceae. Additionally, increasing levels of β-glucanase in the diet of nursery pigs affected (Quadratic; \( P < 0.05 \)) the relative abundance of others (maximum 4.70\% at 382 U/kg feed), whereas β-glucanase supplementation tended to increase (\( P = 0.051 \)) the abundance when compared to the diet without β-glucanase supplementation (0 vs. others).

At the genus level (Table 5), increasing levels of β-glucanase in the diet of nursery pigs affected (Quadratic; \( P < 0.05 \)) the relative abundance of Prevotella (maximum 19.01\% at 399 U/kg feed) and tended to reduce the relative abundance of Streptococcus (Linear; \( P = 0.083 \)) and Campylobacter (Linear; \( P = 0.074 \)). β-glucanase supplementation reduced (\( P < 0.05 \)) the relative abundance Campylobacter when compared to the diet lacking β-glucanase (0 vs. others). Additionally, increasing levels of β-glucanase in the diet of nursery pigs increased (Linear; \( P < 0.05 \)) the relative abundance of Faecalibacterium. Increasing levels of β-glucanase in the diet of nursery pigs affected (Quadratic; \( P < 0.05 \)) the relative abundance of Others (maximum 5.35\% at 380 U/kg feed), whereas β-glucanase supplementation tended
to increase \((P = 0.072)\) the abundance when compared to the diet lacking β-glucanase (0 vs. others).

At the species level (Table 6), increasing levels of β-glucanase in the diet of nursery pigs affected (Quadratic; \(P < 0.05\)) the relative abundance of \textit{Prevotella copri} (maximum 22.71% at 410 U/kg feed) and \textit{Prevotella_sp} (maximum 2.89% at 373 U/kg feed). Increasing levels of β-glucanase tended to reduce (Linear; \(P = 0.094\)) the relative abundance of \textit{Streptococcus alactolyticus}, reduced (Linear; \(P < 0.05\)) the relative abundance of \textit{Helicobacter rappini}, and increased (Linear; \(P < 0.05\)) the relative abundance of \textit{Faecalibacterium prausnitzii}. Additionally, increasing levels of β-glucanase tended to affect (Quadratic; \(P = 0.056\)) the relative abundance of \textit{Selenomonas bovis} (minimum 1.00% at 312 U/kg feed). The relative abundance of \textit{Roseburia faecis} also tended to increase \((P = 0.098)\) with dietary β-glucanase supplementation.

The alpha diversity of jejunal mucosa-associated microbiota estimated with Chao1 richness, Shannon diversity, and Simpson diversity was not affected by dietary β-glucanase supplementation (Table 7).

\textit{Immune and Oxidative Stress Status}

Increasing levels of β-glucanase supplementation did not affect the concentrations of TNF-α, IL-6 and MDA in mucosa of jejunum and colon (Table 8). However, increasing levels of β-glucanase in the diet of pigs tended to reduce (Linear; \(P = 0.076\)) the concentration of TNF-α and reduced (Linear; \(P < 0.05\)) the concentration of IL-6 in plasma. The concentration of MDA in plasma was not affected by dietary treatments.

\textit{Histomorphology, Immunohistochemistry, and Digesta Viscosity}

Increasing levels of β-glucanase increased the villus height (Linear; \(P < 0.05\)) and tended to affect (Quadratic; \(P = 0.073\)) the percentage of Ki-67 positive cells in the mid-jejunum of pigs (Table 9). Increasing levels of β-glucanase did not affect the villus width,
crypt depth, and VH:CD ratio. Increasing levels of β-glucanase in the diets of nursery pigs did not affect the viscosity of digesta collected from the distal jejunum.

Digestibility

The increasing levels of β-glucanase did not affect the AID or ATTD of DM and EE in the diets of nursery pigs (Table 10). However, β-glucanase supplementation (0 vs. others) tended to increase (P = 0.096) the AID of CP in diet of nursery pigs. In addition, increasing levels of β-glucanase tended to increase (Linear; P = 0.097) the ATTD of GE in diet of nursery pigs.

Correlation with Mucos-Associate Microbioa

Mycoplasmataceae was positively correlated with the concentration of MDA in the colonic mucosa (r = 0.37; P < 0.05), whereas it was negatively correlated with the AID of DM (r = -0.38; P < 0.05), and GE (r = -0.35; P < 0.05) (Table 11). Similarly, Mycoplasma sualvi was negatively correlated with the AID of DM (r = -0.40; P < 0.05), and GE (r = -0.37; P < 0.05). Campylobacteraceae was negatively correlated with ADG (r = -0.33; P < 0.05). Similarly, Campylobacter coli was negatively correlated with the final BW (r = -0.42; P < 0.05), ADG (r = -0.46; P < 0.05), and ADFI (r = -0.43; P < 0.05). However, Campylobacter coli was positively correlated with AID of DM (r = 0.35; P < 0.05) and GE (r = 0.35; P < 0.05). Enterobacteriaceae was negatively correlated with the VH:CD in jejunum (r = -0.33; P < 0.05). Helicobacter mastomyrinus was positively correlated with the concentration of MDA in the jejunal mucosa (r = 0.37; P < 0.05). Helicobacter rappini Helicobacter equorum were positively correlated with the concentration of TNF-α in the jejunal mucosa (r = 0.50, r = 0.32; P < 0.05, respectively). Lactobacillus delbrueckii and Lactobacillus_sp. were positively correlated with the VH:CD in the jejunal mucosa (r = 0.40, r = 0.42; P < 0.05, respectively).
DISCUSSION

In this study, increasing levels of β-glucanase within the corn soybean meal-based diet supplemented with 30% corn DDGS in combination with xylanase showed a trend to improve the growth performance and effectively affect the intestinal microbiota reducing, therefore, the systemic inflammatory status of nursery pigs. The trend to improve the growth performance from d 14 to 21 of the experiment by increasing ADG occurred without an alteration in ADFI or feed efficiency. The use of dietary xylanase or β-glucanase in swine diets have been reported to be effective in reducing digesta viscosity, affecting the intestinal microbiota and enhancing the intestinal health (Duarte et al., 2019; Chen et al., 2020; Petry et al., 2020). The improvement in the intestinal environment can further increased the digestibility of nutrients, and consequently the growth performance of pigs (Ji et al., 2008; Duarte et al., 2019; Chen et al., 2020). Whereas, these parameters have been shown to be further improved with the inclusion of β-glucanase combined with xylanase due to the variety of NSP present in plant-based diets (Mathlouthi et al., 2002b; Knudsen, 2014; Tsai et al., 2017). The composition and structure of cell wall in cereal grains vary depending on different parts in the grain (Dien et al., 2005; Yoshida et al., 2012). The concentration of xylan in the pericarp is greater than in the endosperm (Dien et al., 2005). In addition, the cellulose microfibrils in the cell wall are embedded in arabinoxylans, β-glucans, and structural proteins (Chandrashekar and Mazhar, 1999; Stone et al., 2010; Kiemle et al., 2014). Therefore, it can be suggested that feeding a blend of enzymes may be more effective on reducing the anti-nutritional effect of NSP in the diet of nursery pigs.

In the current study, pigs were fed a basal diet with an increased fiber content (9.5% NDF and 3.8% ADF). It is well known that high fiber diets can increase the digesta viscosity, reducing the digestibility of nutrients (Chen et al., 2020; Hung et al., 2021). The main functions of β-glucanase and xylanase are to hydrolyze the polymers β-glucan and xylans,
respectively, therefore reducing their capacity to increase digesta viscosity and increasing their fermentability by the microbiota (Passos et al., 2015; Duarte et al., 2019; Chen et al., 2020; Petry et al., 2020). In addition, hydrolysis of NSP in the cell wall can release nutrients encapsulated within the cell (Bedford and Partridge, 2000; Baker et al., 2021). The lower viscosity and released nutrients can increase the interaction of the enzymes and substrates resulting in increased digestion and absorption of nutrients. Increasing levels of β-glucanase in diets did not further reduce digesta viscosity in this study possibility because all diets contained xylanase at the same level. However, it showed a trend to increase the AID of CP and the ATTD of GE. These results indicate that enhancement of AID of CP could also be associated with the capacity of NSP-degrading enzymes to release nutrients from the cells in the small intestine. In addition, Fan et al. (2009) reported that β-glucanase and xylanase supplementation increased the activities of pepsin in gastric mucosa and γ-glutamyl transpeptidase, and disaccharidases in jejunal and ileal mucosa of weaned pigs fed barley-based diet. The hydrolysis of NSP releases oligosaccharides, increasing the fermentability of the dietary fiber by microbes and production of short-chain fatty acids (SCFA) along the intestine (Lafond et al., 2012; Masey-O’Neill et al., 2014) that can then be rapidly absorbed by epithelial cells, effectively altering energy metabolism (Den Besten et al., 2013; Nakatani et al., 2018). This process can partly explain the improvement in ATTD of GE seen in the present study.

The changes in the physicochemical properties of dietary fiber and the resulting nutrient availability caused by the use of NSP-degrading enzymes (Ji et al., 2008; Passos et al., 2015; Chen et al., 2020) alter the environment in the intestinal lumen, leading to a shift toward a more beneficial microbiota (Munyaka et al., 2016; Zhang et al., 2018; Akkerman et al., 2020). The change in the environment of the small intestine may partially explain the modulation of the mucosa-associated microbiota among treatments observed in this study.
Adhikari et al. (2019) have demonstrated that the microbiota in the lumen of jejunum differ from those associated with the mucosa. The jejunum is the major site for digestion and absorption of AA, energy, and fat with a considerable amount of fiber fermentation (Chen et al., 2020; Mace and Marshall, 2013; Passos et al., 2015; Tiwari et al., 2018). In addition to the digestive functions, the jejunum plays important role in the immune system. According to Wiarda et al. (2020), the immune cells are more abundant in the jejunum than in the large intestine in nursery pigs. According to Petry et al. (2020) the interaction among diet, microbiota, and immune system responses are more effective in the small intestine. In addition, it has been demonstrated that the mucosa-associated microbiota directly crosstalk with intestinal immune cells (Arpaia et al., 2013; Belkaid and Hand, 2014; Mulder et al., 2011) leading to a greater capability on immunological regulation (Mu et al., 2017).

Furthermore, the mucosa-associated microbiota is greatly susceptible to dietary influence in the small intestine of pigs (Levesque et al., 2012, 2014). Therefore, considering the digestive functions and the physicochemical properties in the small intestine, Duarte and Kim (2021) have showed that the mucosa of the jejunum could be considered a key site to evaluate the diet, intestinal microbiota, and intestinal health interaction.

In this study, increasing levels of β-glucanase within diets containing xylanase reduced the abundance of the proteolytic bacteria Helicobacter rappini and increased the abundance of the fiber-degrading families Prevotellaceae, Lachnospiraceae, and Ruminococcaceae. Increasing the AID of CP results in a reduction of the availability of undigested protein for microbial fermentation, therefore reducing the abundance of proteolytic bacteria. In addition, the oligosaccharides released by xylanase and β-glucanase can modulate the mucosa-associated microbiota by selectively increasing the abundance of fiber-degrading bacteria (Baker et al. 2021; Munyaka et al. 2016; Petry et al., 2021). A lower abundance of proteolytic bacteria such as Helicobacter spp. have been correlated to improved
health status in pigs (Dowd et al., 2008; Duarte et al., 2020). Protein fermentation releases a broad range of metabolites within the gastrointestinal tract (GIT) that can be harmful to the host by affecting the immune response and intestinal permeability (Richter et al., 2014; Villodre Tudela et al., 2015). Interestingly, fiber fermentation is more related to the production of SCFA by bacteria such as Lachnospiraceae and Ruminococcaceae (Venegas et al., 2019). In pigs fed plant-based diets, increasing abundance of the family Prevotellaceae, which belongs to the phylum Bacteroidetes, in the intestinal mucosa pigs has indicated enhanced healthy status of the host (Adhikari et al., 2019; Duarte et al., 2020).

The increase in the relative abundance of the family Ruminococcaceae might be attributed to the increase of the species Faecalibacterium prausnitzii, which has been identified as a potential probiotic for humans due to its benefits to the host, namely its anti-inflammatory properties (Martín et al., 2017). Faecalibacterium prausnitzii is a Gram-negative bacteria lacking lipopolysaccharides (LPS) within its cell wall with a variety numbers of anti-inflammatory mechanisms (Miquel et al., 2013; Qiu et al., 2013; Zhang et al., 2021). Faecalibacterium prausnitzii directly cross-talk with the epithelial cells by secreting metabolites that further affect the immune system (Zhang et al., 2021). Butyric acid is produced by F. prausnitzii (Ganesan et al., 2018), utilizing mainly acetic acid as substrate (Louis et al., 2007) and therefore its growth is generally attributed to acetic acid-producing bacteria such as Lactobacillus and Bifidobacterium (Miquel et al., 2014). Butyric acid has been shown to promote improved intestinal health in nursery pigs reducing the concentration of TNF-α and IFN-γ (Wen et al., 2012; Diao et al., 2019; Zhong et al., 2019). In addition, the metabolites produced by F. prausnitzii possess anti-inflammatory effects that are able to block NF-κB activation and the IL-8 production (Sokol et al., 2008; Miquel et al., 2015) by downregulating Toll-like receptors 3 and 4 (TLR3 and TLR4) in intestinal mucosa (Zhang et al., 2021). Therefore, the supplementation of β-glucanase within the diet in combination with
xylanase modulated the jejunal mucosa-associated microbiota leading to a reduction in the systemic inflammatory status of nursery pigs.

β-glucans can directly affect the immune system by binding receptors in the intestine and increasing Dectin-1 stimulation (Kanjan et al., 2017). Dectin-1 activates the immune response, effectively stimulating the production of pro-inflammatory cytokines (Sahasrabudhe et al., 2016; Kanjan et al., 2017). After enzymatic treatment of NSP-containing feed ingredients, these effects are even more pronounced (Sahasrabudhe et al., 2016). Whereas, β-glucans can affect the adherence of bacteria in the epithelial cells further affecting the immune response (Arena et al., 2016). In the present study the systemic inflammatory status was linearly enhanced by reducing the concentration of IL-6 and TNFα in the plasma, possibly due to the modulation of the microbiota. According to Kreuzer et al. (2012), metabolites produced by protein fermentation upregulate the expression of IL-6, therefore a reduction of proteolytic bacteria may have contributed to the reduction of IL-6 seen in the present study. In addition, the shift in the microbiota could have affected the production of SCFA that have been shown to inhibit inflammation within the intestine of pigs (Wen et al., 2012). In light of this, evaluating the role of NSP-degrading enzymes on inflammatory status should also take into account the interaction between fiber fermentation and protein availability on the intestinal microbiota, considering the modulation in the microbiota composition (Pieper et al., 2012; Richter et al., 2014). Therefore, β-glucanase within the diet with xylanase can reduce the systemic inflammation of nursery pigs.

Although the increasing β-glucanase supplementation did not affect the immune and oxidative stress status on jejunal mucosa, the enhancement of the immune status parameters in serum may have reduced the epithelial damage by enhancing the status of intestinal environment, reducing the deleterious effect of the dietary fiber, and consequently increasing the villus height on nursery pigs in this study. In addition, the greater villus height can be a
consequence of a greater enterocyte proliferation rate (Wang et al., 2019; Zhong et al., 2019). Conversely, Duarte et al. (2020) reported that lower villus height is correlated with greater cell proliferation rate. In this study, the enterocyte proliferation rate, indicated by the percent of Ki-67\(^+\) crypt cells, showed a quadratic effect with the increasing \(\beta\)-glucanase supplementation. This result indicates that the \(\beta\)-glucanase supplementation increased the cell proliferation by enhancing the status of intestinal environment and increasing the abundance of butyric acid-producing bacteria (Zhong et al., 2019). According to Knudsen et al. (2012) some fatty acids in the lumen stimulate the enterocyte proliferation. The enhancement in the intestinal barrier function can also be attributed to the increased abundance of \textit{Faecalibacterium prausnitzii} in jejunal mucosa due to its anti-inflammatory effects (Zhang et al., 2021). Therefore, enhancing the status of intestinal environment can be associated with the improvement of the intestinal integrity.

In this study, considerable changes in the microbiota by supplemental blend of enzymes led to a reduction in the systemic immune response and an enhancement in the intestinal structure, which in turn caused a tendency increase of the growth performance of pigs. The correlation test showed that the growth performance was negatively correlated with \textit{Campylobacter coli}, which belongs to the family Campylobacteraceae. The VH:CD was negatively correlated with Enterobacteriaceae and \textit{Helicobacter rappini}, whereas it was positively correlated with \textit{Lactobacillus} spp.. The concentration of TNF\(\alpha\) in jejunum was positively correlated with Enterobacteriaceae and \textit{Helicobacter} spp.. The concentration of MDA in the jejunum was positively correlated with \textit{Helicobacter mastomyrinus}. The AID of DM and GE were negatively correlated with \textit{Mycoplasma sualvi}. The bacteria correlated with growth performance, intestinal health, and digestibility related in this study, were previously reported by Duarte and Kim (2021) as key microbiota. Considering that growth performance is a multifactorial variable, it can be suggested that the shift of the microbiota should affect
other parameters first and then affect growth performance indirectly. As recently suggested by Petry et al. (2020), a longer adaptation period is needed for testing xylanase supplementation for pigs. The initial BW of pigs was 12.3 kg in this study; at this age the microbiota has increased the ability to handle NSP within diets (Niu et al. 2015; Ke et al., 2019). This emphasizes the importance of further experiments to determine specific metabolites in the context of long-term dietary NSP-degrading enzyme supplementation, considering dietary fiber intake, age of pigs, the microbiota profile at the beginning of the study as well as the duration of the study.

In conclusion, increasing β-glucanase up to 600 U/kg feed in a diet containing xylanase (1,500 EPU/kg feed) modulated mucosa-associated microbiota by increasing the relative abundance of beneficial bacteria and reducing potentially harmful bacteria. Furthermore, increasing β-glucanase up to 600 U/kg feed in a diet containing xylanase (1,500 EPU/kg feed) enhanced the status of intestinal environment and the nutrient utilization as well as reduced the systemic inflammation of pigs, collectively resulting in a moderate improvement of growth performance. Supplementing β-glucanase at a range of 312 to 410 U/kg feed with xylanase at 1,500 EPU/kg feed showed the most benefit on mucosa-associated microbiota in the jejunum and reduced systemic inflammation of pigs.

Table 1. Composition of experimental diets\(^1\) (as-fed basis)

| Ingredient, % | Basal diet |
|---------------|------------|
| Corn grain    | 39.28      |
| Soybean meal  | 26.00      |
| Corn DDGS     | 30.01      |
| Poultry fat   | 2.00       |
| L-Lys HCl     | 0.40       |
| DL-Met        | 0.02       |
| L-Thr         | 0.02       |
| Salt          | 0.22       |
| Vitamin premix\(^2\) | 0.03 |
| Mineral premix\(^3\) | 0.15 |
| Dical phosphate | 0.61 |
| Limestone     | 1.25       |
| Xylanase + β-glucanase\(^1\) | 0.01 |
| Phytase\(^4\) | 0.03       |
| Total         | 100.00     |

Calculated composition

|          |          |
|----------|----------|
| Dry matter, % | 89.60    |
| ME, Mcal/kg  | 3.40     |
| SID\(^5\) Lys, % | 1.24   |
| Arabinoxylan\(^6\), % | 6.92 |
| β-glucan\(^7\), % | 1.95   |
| Ca, %      | 0.72     |
| STTD\(^8\) P, % | 0.33   |
| Total P, %  | 0.58     |

Analyzed composition

|          |          |
|----------|----------|
| Dry matter, % | 90.91    |
| Crude protein, % | 21.14   |
| Crude fat, %  | 5.53     |
| Neutral detergent fiber, % | 9.49    |
| Acid detergent fiber, %  | 3.77     |

\(^1\) Dietary treatments: β-glucanase providing 0, 200, 400, or 600 U/kg of feed. Mixtures of Hostazym X 100 (Huvepharma, Peachtree City, GA) to provide 1,500 EPU xylanase/kg of feeds for all treatments and β-glucanase to provide 0, 200, 400, and 600 U of β-glucanase/kg of feed for each treatment were pre-mixed to have an equal inclusion level of 0.01% for all treatments. The analyzed enzyme activity in the premixes supplemented to experimental diets were: Premix 1 (xylanase: 19,600 EPU/g; β-glucanase: 2,300 U/g); Premix 2 (xylanase: 18,900 EPU/g and β-glucanase: 2,300 U/g); Premix 3 (xylanase: 18,100 EPU/g and β-glucanase: 3,700 U/g); and Premix 4 (xylanase: 18,500 EPU/g and β-glucanase: 6,700 U/g).

\(^2\) The vitamin premix provided the following per kilogram of complete diet: 6,613.8 IU of vitamin A as vitamin A acetate, 992.0 IU of vitamin D3, 19.8 IU of vitamin E, 2.64 mg of vitamin K, 37.4 mg of niacin, 10.0 mg of pantothenic acid, 1.5 mg of biotin, 2.0 mg of choline, and 2.4 mg of folic acid.
vitamin K as menadione sodium bisulfate, 0.03 mg of vitamin B12, 4.63 mg of riboflavin, 18.52 mg of D-pantothenic acid as calcium pantothenate, 24.96 mg of niacin, and 0.07 mg of biotin.

3 The trace mineral premix provided the following per kilogram of complete diet: 4.0 mg of Mn as manganous oxide, 165 mg of Fe as ferrous sulfate, 165 mg of Zn as zinc sulfate, 16.5 mg of Cu as copper sulfate, 0.30 mg of I as ethylenediamine di-hydroiodide, and 0.30 mg of Se as sodium selenite.

4 OptiPhos 2000 was used as phytase (Huvepharma) at 0.025% to provide 500 FTU/kg feed.

5 SID, standardized ileal digestible.

6 Arabinoxylan content calculated according to Jaworski et al. (2015) and Tiwari et al. (2018)

7 β-glucan content calculated according to Sampson et al. (2015) and Yu et al. (2018)

8 STTD P, standardized total tract digestible phosphorus.
Table 2. Growth performance of pigs fed diet with β-glucanase

| Item         | β-glucanase, U/kg feed |  |  |  | SEM | Linear | Quadratic | 0 vs. others |
